Preface

The history of Automatic Control is both ancient and modern. If we adopt the broad view that an automatic control system is any mechanism by which an input action and output action are dynamically coupled, then the origins of this encyclopedia's subject matter may be traced back more than 2,000 years to the era of primitive time-keeping and the clepsydra water clock perfected by Ctesibius of Alexandria. In more recent history, frequently cited examples of feedback control include the automatically refilling reservoirs of flush toilets (perfected in the late nineteenth century) and the celebrated fly-ball steam-flow governor described in J.C. Maxwell's 1868 Royal Society of London paper—"On Governors."

Although it is useful to keep the technologies of antiquity in mind, the history of systems and control as covered in the pages of this encyclopedia begins in the twentieth century. The history was profoundly influenced by work of Nyqvist, Black, Bode, and others who were developing amplifier theory in response to the need to transmit wireline signals over long distances. This research provided major conceptual advances in feedback and stability that proved to be of interest in the theory of servomechanisms that was being developed at the same time. Driven by the need for fast and accurate control of weapons systems during World War II, automatic control developed quickly as a recognizable discipline.

While the developments of the first half of the twentieth century are an important backdrop for the *Encyclopedia of Systems and Control*, most of the topics directly treat developments from 1948 to the present. The year 1948 was auspicious for systems and control—and indeed for all the information sciences. Norbert Wiener's book *Cybernetics* was published by Wiley, the transistor was invented (and given its name), and Shannon's seminal paper "A Mathematical Theory of Communication" was published in the *Bell System Technical Journal*. In the years that followed, important ideas of Shannon, Wiener, Von Neumann, Turing, and many others changed the way people thought about the basic concepts of control systems. The theoretical advances have propelled industrial and societal impact as well (and vice versa). Today, advanced control is a crucial enabling technology in domains as numerous and diverse as aerospace, automotive, and marine vehicles; the process industries and manufacturing; electric power systems; homes and buildings; robotics; communication networks; economics and finance; and biology and biomedical devices.

It is this incredible broadening of the scope of the field that has motivated the editors to assemble the entries that follow. This encyclopedia aims to help students, researchers, and practitioners learn the basic elements of a vast array of topics that are now considered part of systems and control. The goal is to provide entry-level access to subject matter together with cross-references to related topics and pointers to original research and source material.

Entries in the encyclopedia are organized alphabetically by title, and extensive links to related entries are included to facilitate topical reading—these links are listed in "Cross-References" sections within entries. All cross-referenced entries are indicated by a preceding symbol: ▶. In the electronic version of the encyclopedia these entries are hyperlinked for ease of access.

The creation of the *Encyclopedia of Systems and Control* has been a major undertaking that has unfolded over a 3-year period. We owe an enormous debt to major intellectual leaders in the field who agreed to serve as topical section editors. They have ensured the value of the opus by recruiting leading experts in each of the covered topics and carefully reviewing drafts. It has been a pleasure also to work with Oliver Jackson and Andrew Spencer of Springer, who have been unfailingly accommodating and responsive over this time.

As we reflect back over the course of this project, we are reminded of how it began. Gary Balas, one of the world's experts in robust control and aerospace applications, came to one of us after a meeting with Oliver at the Springer booth at a conference and suggested this encyclopedia—but was adamant that he wasn't the right person to lead it. The two of us took the initiative (ultimately getting Gary to agree to be the section editor for the aerospace control entries). Gary died last year after a courageous fight with cancer. Our sense of accomplishment is infused with sadness at the loss of a close friend and colleague.

We hope readers find this encyclopedia a useful and valuable compendium and we welcome your feedback.

Active Power Control of Wind Power Plants for Grid Integration

Lucy Y. Pao
University of Colorado, Boulder, CO, USA

Abstract

Increasing penetrations of intermittent renewable energy sources, such as wind, on the utility grid have led to concerns over the reliability of the grid. One approach for improving grid reliability with increasing wind penetrations is to actively control the real power output of wind turbines and wind power plants. Providing a full range of responses requires derating wind power plants so that there is headroom to both increase and decrease power to provide grid balancing services and stabilizing responses. Initial results indicate that wind turbines may be able to provide primary frequency control and frequency regulation services more rapidly than conventional power plants.

Keywords

Active power control; Automatic generation control; Frequency regulation; Grid balancing; Grid integration; Primary frequency control; Wind energy

Balancing Electrical Generation and Load on the Grid

Wind penetration levels across the world have increased dramatically, with installed capacity growing at a mean annual rate of 25 % over the last decade (Gsanger and Pitteloud 2013). Some nations in Western Europe, particularly Denmark, Portugal, Spain, and Germany, have seen wind provide more than 16 % of their annual electrical energy needs (Wiser and Bolinger 2013). To maintain grid frequency at its nominal value, the electrical generation must equal the electrical load on the grid. This balancing has historically been left up to conventional utilities with synchronous generators, which can vary their active power output by simply varying their fuel input. Grid frequency control is performed across a number of regimes and time scales, with both manual and automatic control commands. Further details can be found in Rebours et al. (2007) and Ela et al. (2011).

Wind turbines and wind power plants are now being recognized as having the potential to meet demanding grid stabilizing requirements set by transmission system operators (Aho et al. 2013a,b; Buckspan et al. 2012; Ela et al. 2011; Miller et al. 2011). Recent grid code requirements have spurred the development of wind turbine active power control (APC) systems, which allow wind turbines to participate in grid frequency regulation and provide stabilizing responses to

sudden changes in grid frequency. The ability of wind turbines to provide APC services also allows them to follow forecast-based power production schedules.

For a wind turbine to fully participate in grid frequency control, it must be derated (to P_{derated}) with respect to the maximum power (P_{max}) that can be generated given the available wind, allowing for both increases and decreases in power, if necessary. Wind turbines can derate their power output by pitching their blades to shed aerodynamic power or reducing their generator torque in order to operate at higher-than-optimal rotor speeds. Wind turbines can then respond at different time scales to provide more or less power through pitch control (which can provide a power response within seconds) and generator torque control (which can provide a power response within milliseconds).

Wind Turbine Inertial and Primary Frequency Control

Inertial and primary frequency control is generally considered to be the first 5–10 s after a frequency event occurs. In this regime, the governors of capable utilities actuate, allowing for a temporary increase or decrease in the utilities' power outputs. The primary frequency control (PFC) response provided by conventional synchronous generators can be characterized by a droop curve, which relates fluctuations in grid frequency to a change in power from the utility. For example, a 3 % droop curve means that a 3 % change in grid frequency yields a 100 % change in commanded power.

Although modern wind turbines do not inherently provide inertial or primary frequency control responses because their power electronics impart a buffer between their generators and the grid, such responses can be produced through careful design of the wind turbine control systems. While the physical properties of a conventional synchronous generator yield a static droop characteristic, a wind turbine can be controlled to provide a primary frequency response via either a static or time-varying droop curve.
Active Power Control of Wind Power Plants for Grid Integration, Fig. 1 Simulation results showing the capability of wind power plants to provide APC services on a small-scale grid model. The total grid size is 3 GW, and a frequency event is induced due to the sudden active power imbalance when 5 % of generation is taken offline at time = 200 s. Each wind power plant is derated to 90 % of its rated capacity. The system response with all conventional generation (no wind) is compared to the cases when there are wind power plants on the grid at 10 % penetration (i) with a baseline control system (wind baseline) where wind does not provide APC services and (ii) with an APC system (wind APC) that uses a 3 % droop curve where either 50 % or 100 % of the wind power plants provide PFC

A time-varying droop curve can be designed to be more aggressive when the magnitude of the rate of change of frequency of the grid is larger.

Figure 1 shows a simulation of a grid response under different scenarios when 5 % of the generating capacity suddenly goes offline. When the wind power plant (10 % of the generation on the grid) is operating with its normal baseline control system that does not provide APC services, the frequency response is worse than the no-wind scenario, due to the reduced amount of conventional generation in the wind-baseline scenario that can provide power control services. However, compared to both the no-wind and wind-baseline cases, using PFC with a droop curve results in the frequency decline being arrested at a minimum (nadir) frequency f_{nadir} that is closer to the nominal $f_{\text{nom}} = 60$ Hz frequency level; further, the steady-state frequency f_{ss} after the PFC response is also closer to f_{nom}. It is important to prevent the difference $f_{\text{nom}} - f_{\text{nadir}}$

from exceeding a threshold that can lead to underfrequency load shedding (UFLS) or rolling blackouts. The particular threshold varies across utility grids, but the largest such threshold in North America is 1.5 Hz.

Stability issues arising from the altered control algorithms must be analyzed (Buckspan et al. 2013). The trade-offs between aggressive primary frequency control and resulting structural loads also need to be evaluated carefully. Initial research shows that potential grid support can be achieved while not causing any increases in structural loading and hence fatigue damage and operations and maintenance costs (Buckspan et al. 2012).

Wind Turbine Automatic Generation Control

Secondary frequency control, also known as automatic generation control (AGC), occurs on a slower time scale than PFC. AGC commands can be generated from highly damped proportional integral (PI) controllers or logic controllers to regulate grid frequency and are used to control the power output of participating power plants. In many geographical regions, frequency regulation services are compensated through a competitive market, where power plants that provide faster and more accurate AGC command tracking are paid more.

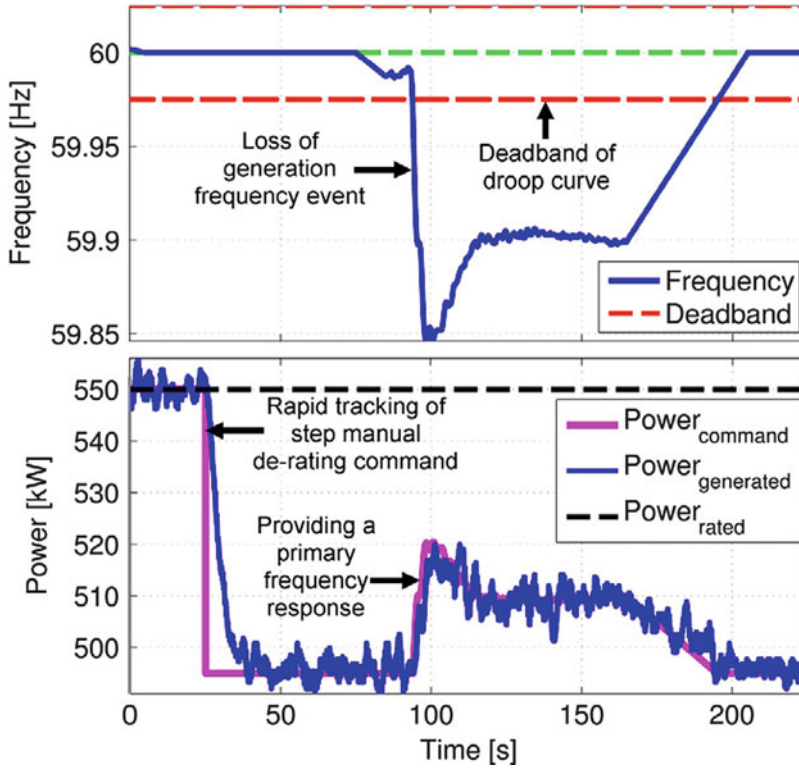
An active power control system that combines both primary and secondary/AGC frequency control capabilities has recently been detailed in Aho et al. (2013a). Figure 2 presents initial experimental field test results of this active power controller, in response to prerecorded frequency events, showing how responsive wind turbines can be to both manual derating commands as well as rapidly changing automatic primary frequency control commands generated via a droop curve. Overall, results indicate that wind turbines can respond more rapidly than conventional power plants. However, increasing the power control and regulation performance of a wind turbine should be carefully considered due to a number of complicating factors, including coupling with

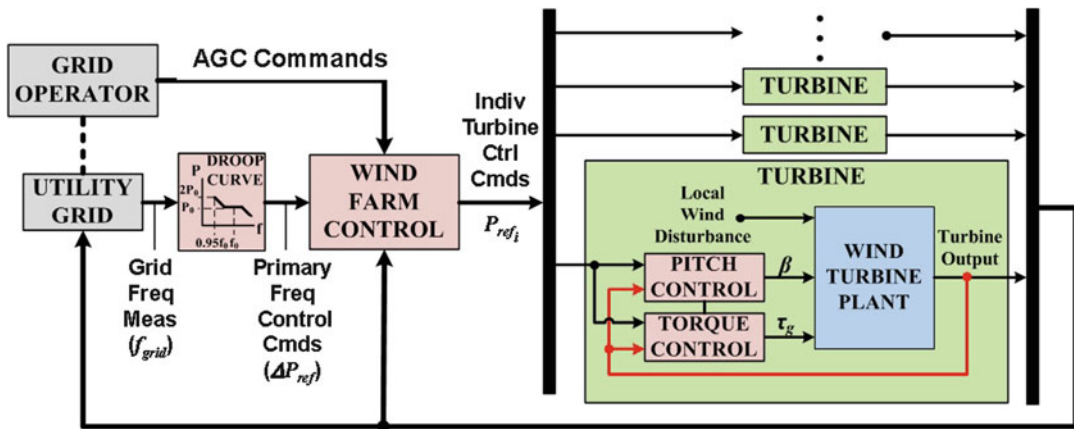
existing control loops, a desire to limit actuator usage and structural loading, and wind variability.

Active Power Control of Wind Power Plants

A wind power plant, often referred to as a wind farm, consists of many wind turbines. In wind power plants, wake effects can reduce generation in downstream turbines to less than 60 % of the lead turbine (Barthelmie et al. 2009; Porté-Agel et al. 2013). There are many emerging areas of active research, including the modeling of wakes and wake effects and how these models can then be used to coordinate the control of individual turbines so that the overall wind power plant can reliably track the desired power reference command. A wind farm controller can be interconnected with the utility grid, transmission system operator (TSO), and individual turbines as shown in Fig. 3. By properly accounting for the wakes, wind farm controllers can allocate appropriate power reference commands to the individual wind turbines. Individual turbine generator torque and blade pitch controllers, as discussed earlier, can be designed so that each turbine follows the power reference command issued by the wind farm controller. Methods for intelligent, distributed control of entire wind farms to rapidly respond to grid frequency disturbances could significantly reduce frequency deviations and improve recovery speed to such disturbances.

Combining Techniques with Other Approaches for Balancing the Grid

Ultimately, active power control of wind turbines and wind power plants should be combined with both demand-side management and storage to provide a more comprehensive solution that enables balancing electrical generation and electrical load with large penetrations of wind energy on the grid. Demand-side management (Callaway and Hiskens 2011; Kowli and Meyn 2011; Palensky and Dietrich 2011)


Active Power Control of Wind Power Plants for Grid Integration, Fig. 2 The frequency data input and power that is commanded and generated during a field test with a 550 kW research wind turbine at the US National Renewable Energy Laboratory (NREL). The frequency data was recorded on the Electric Reliability Council of Texas (ERCOT) interconnection (data courtesy of Vahan Gevorgian, NREL). The upper plot shows the grid frequency, which is passed through a 5 % droop curve with a deadband to generate a power command. The high-frequency fluctuations in the generated power would be smoothed when aggregating the power output of an entire wind power plant


Active Power Control of Wind Power Plants for Grid Integration, Fig. 3 Schematic showing the communication and coupling between the wind farm control system, individual wind turbines, utility grid, and the grid operator. The wind farm controller uses measurements of the utility grid frequency and automatic generation control power command signals from the grid operator to determine a power reference for each turbine in the wind farm

aims to alter the demand in order to mitigate peak electrical loads and hence to maintain sufficient control authority among generating units. As more effective and economical energy storage solutions (Pickard and Abbott 2012) at the power plant scale are developed, wind (and solar) energy can then be stored when wind (and solar) energy availability is not well matched with electrical demand. Advances in wind forecasting (Giebel et al. 2011) will also improve wind power forecasts to facilitate more accurate scheduling of larger amounts of wind power on the grid.

Adaptive Control of Linear Time-Invariant Systems

Petros A. Ioannou
University of Southern California, Los Angeles, CA, USA

Abstract

Adaptive control of linear time-invariant (LTI) systems deals with the control of LTI systems whose parameters are constant but otherwise completely unknown. In some cases, large norm bounds as to where the unknown parameters are located in the parameter space are also assumed to be known. In general, adaptive control deals with LTI plants which cannot be controlled with fixed gain controllers, i.e., nonadaptive control methods, and their parameters even though assumed constant for design and analysis purposes may change over time in an unpredictable manner. Most of the adaptive control approaches for LTI systems use the so-called certainty equivalence principle where a control law motivated from the known parameter case is combined with an adaptive law for estimating on line the unknown parameters. The control law could be associated with different control objectives and the adaptive law with different parameter estimation techniques. These combinations give rise to a wide class of adaptive control schemes. The two popular control objectives that led to a wide range of adaptive control schemes include model reference adaptive control (MRAC) and adaptive pole placement control (APPC). In MRAC, the control objective is for the plant output to track the output of a reference model, designed to represent the desired properties of the plant, for any reference input signal. APPC is more general and is based on control laws whose objective is to set the poles of the closed loop at desired locations chosen based on performance requirements. Another class of adaptive controllers for LTI systems that involves ideas from MRAC and APPC
is based on multiple models, search methods, and switching logic. In this class of schemes, the unknown parameter space is partitioned to smaller subsets. For each subset, a parameter estimator or a stabilizing controller is designed or a combination of the two. The problem then is to identify which subset in the parameter space the unknown plant model belongs to and/or which controller is a stabilizing one and meets the control objective. A switching logic is designed based on different considerations to identify the most appropriate plant model or controller from the list of candidate plant models and/or controllers. In this entry, we briefly describe the above approaches to adaptive control for LTI systems.

Keywords

Adaptive pole placement control; Direct MRAC; Indirect MRAC; LTI systems; Model reference adaptive control; Robust adaptive control

Model Reference Adaptive Control

In model reference control (MRC), the desired plant behavior is described by a reference model which is simply an LTI system with a transfer function $W_m(s)$ and is driven by a reference input. The controller transfer function $C(s, \theta^*)$, where θ^* is a vector with the coefficients of $C(s)$, is then developed so that the closed-loop plant has a transfer function equal to $W_m(s)$. This transfer function matching guarantees that the plant will match the reference model response for any reference input signal. In this case the plant transfer function $G_p(s, \theta_p^*)$, where θ_p^* is a vector with all the coefficients of $G_p(s)$, together with the controller transfer function $C(s, \theta^*)$ should lead to a closed-loop transfer function from the reference input r to the plant output y_p that is equal to $W_m(s)$, i.e.,

$$\frac{y_p(s)}{r(s)} = W_m(s) = \frac{y_m(s)}{r(s)}, \qquad (1)$$

where y_m is the output of the reference model. For this transfer matching to be possible, $G_p(s)$ and $W_m(s)$ have to satisfy certain assumptions. These assumptions enable the calculation of the controller parameter vector θ^* as

$$\theta^* = F(\theta_p^*), \qquad (2)$$

where F is a function of the plant parameters θ_p^*, to satisfy the matching equation (1). The function in (2) has a special form in the case of MRC that allows the design of both direct and indirect MRAC. For more general classes of controller structures, this is not possible in general as the function F is nonlinear. This transfer function matching guarantees that the tracking error $e_1 = y_p - y_m$ converges to zero for any given reference input signal r. If the plant parameter vector θ_p^* is known, then the controller parameters θ^* can be calculated using (2), and the controller $C(s, \theta^*)$ can be implemented. We are considering the case where θ_p^* is unknown. In this case, the use of the certainty equivalence (CE) approach, (Astrom and Wittenmark 1995; Egardt 1979; Ioannou and Fidan 2006; Ioannou and Kokotovic 1983; Ioannou and Sun 1996; Landau 1979; Landau et al. 1998; Morse 1996; Narendra and Annaswamy 1989; Narendra and Balakrishnan 1997; Sastry and Bodson 1989; Stefanovic and Safonov 2011; Tao 2003) where the unknown parameters are replaced with their estimates, leads to the adaptive control scheme referred to as *indirect MRAC*, shown in Fig. 1a.

The unknown plant parameter vector θ_p^* is estimated at each time t denoted by $\theta_p(t)$, using an online parameter estimator referred to as adaptive law. The plant parameter estimate $\theta_p(t)$ at each

time t is then used to calculate the controller parameter vector $\theta(t) = F(\theta_p(t))$ used in the controller $C(s, \theta)$. This class of MRAC is called indirect MRAC, because the controller parameters are not updated directly, but calculated at each time t using the estimated plant parameters. Another way of designing MRAC schemes is to parameterize the plant transfer function in terms of the desired controller parameter vector θ^*. This is possible in the MRC case, because the structure of the MRC law is such that we can use (2) to write

$$\theta_p^* = F^{-1}(\theta^*), \qquad (3)$$

where F^{-1} is the inverse of the mapping $F(\cdot)$, and then express $G_p(s, \theta_p^*) = G_p(s, F^{-1}(\theta^*)) = \bar{G}_p(s, \theta^*)$. The adaptive law for estimating θ^* online can now be developed by using $y_p = \bar{G}_p(s, \theta^*)u_p$ to obtain a parametric model that is appropriate for estimating the controller vector θ^* as the unknown parameter vector. The MRAC can then be developed using the CE approach as shown in Fig. 1b. In this case, the controller parameter $\theta(t)$ is updated directly without any intermediate calculations, and for this reason, the scheme is called *direct MRAC*.

The division of MRAC to indirect and direct is, in general, unique to MRC structures, and it is possible due to the fact that the inverse maps in (2) and (3) exist which is a direct consequence of the control objective and the assumptions the plant and reference model are required to satisfy for the control law to exist. These assumptions are summarized below:

Plant Assumptions: $G_p(s)$ is minimum phase, i.e., has stable zeros, its relative degree, $n^* =$
Adaptive Control of Linear Time-Invariant Systems, Fig. 1 Structure of (**a**) indirect MRAC, (**b**) direct MRAC

number of poles−number of zeros, is known and an upper bound n on its order is also known. In addition, the sign of its high-frequency gain is known even though it can be relaxed with additional complexity.

Reference Model Assumptions: $W_m(s)$ has stable poles and zeros, its relative degree is equal to n^* that of the plant, and its order is equal or less to the one assumed for the plant, i.e., of n.

The above assumptions are also used to meet the control objective in the case of known parameters, and therefore the minimum phase and relative degree assumptions are characteristics of the control objective and do not arise because of adaptive control considerations. The relative degree matching is used to avoid the need to differentiate signals in the control law. The minimum phase assumption comes from the fact that the only way for the control law to force the closed-loop plant transfer function to be equal to that of the reference model is to cancel the zeros of the plant using feedback and replace them with those of the reference model using a feedforward term. Such zero pole cancelations are possible if the zeros are stable, i.e., the plant is minimum phase; otherwise stability cannot be guaranteed for nonzero initial conditions and/or inexact cancelations.

The design of MRAC in Fig. 1 has additional variations depending on how the adaptive law is designed. If the reference model is chosen to be strictly positive real (SPR) which limits its transfer function and that of the plant to have relative degree 1, the derivation of adaptive law and stability analysis is fairly straightforward, and for this reason, this class of MRAC schemes attracted a lot of interest. As the relative degree changes to 2, the design becomes more complex as in order to use the SPR property, the CE control law has to be modified by adding an extra nonlinear term. The stability analysis remains to be simple as a single Lyapunov function can be used to establish stability. As the relative degree increases further, the design complexity increases by requiring the addition of more nonlinear terms in the CE control law (Ioannou and Fidan 2006; Ioannou and Sun 1996). The simplicity of using a single Lyapunov function analysis for stability

remains however. This approach covers both direct and indirect MRAC and lead to adaptive laws which contain no normalization signals (Ioannou and Fidan 2006; Ioannou and Sun 1996). A more straightforward design approach is based on the CE principle which separates the control design from the parameter estimation part and leads to a much wider class of MRAC which can be direct or indirect. In this case, the adaptive laws need to be normalized for stability, and the analysis is far more complicated than the approach based on SPR with no normalization. An example of such a direct MRAC scheme for the case of known sign of the high-frequency gain which is assumed to be positive for both plant and reference model is listed below:

Control law:

$$u_p = \theta_1^T(t) \frac{\alpha(s)}{\Lambda(s)} u_p + \theta_2^T \frac{\alpha(s)}{\Lambda(s)} y_p + \theta_3(t) y_p$$

$$+ c_0(t) r = \theta^T(t)\omega, \qquad (4)$$

where $\alpha \triangleq \alpha_{n-2}(s) = [s^{n-2}, s^{n-3}, \ldots, s, 1]^T$ for $n \geq 2$, and $\alpha(s) \triangleq 0$ for $n = 1$, and $\Lambda(s)$ is a monic polynomial with stable roots and degree $n - 1$ having numerator of $W_m(s)$ as a factor.

Adaptive law:

$$\dot{\theta} = \Gamma \varepsilon \phi, \qquad (5)$$

where Γ is a positive definite matrix referred to as the adaptive gain and $\dot{\rho} = \gamma \varepsilon \xi$, $\varepsilon = \frac{e_1 - \rho \xi}{m_s^2}$, $m_s^2 = 1 + \phi^T \phi + u_f^2$, $\xi = \theta^T \phi + u_f$, $\phi = -W_m(s)\omega$, and $u_f = W_m(s) u_p$.

The stability properties of the above direct MRAC scheme which are typical for all classes of MRAC are the following (Ioannou and Fidan 2006; Ioannou and Sun 1996): *(i) All signals in the closed-loop plant are bounded, and the tracking error e_1 converges to zero asymptotically and (ii) if the plant transfer function contains no zero pole cancelations and r is sufficiently rich of order $2n$, i.e., it contains at least n distinct frequencies, then the parameter error $|\tilde{\theta}| = |\theta - \theta^*|$ and the tracking error e_1 converge to zero exponentially fast.*

Adaptive Pole Placement Control

Let us consider the SISO LTI plant:

$$y_p = G_p(s)u_p, \quad G_p(s) = \frac{Z_p(s)}{R_p(s)}, \qquad (6)$$

where $G_p(s)$ is proper and $R_p(s)$ is a monic polynomial. The control objective is to choose the plant input u_p so that the closed-loop poles are assigned to those of a given monic Hurwitz polynomial $A^*(s)$, and y_p is required to follow a certain class of reference signals y_m assumed to satisfy $Q_m(s)y_m = 0$ where $Q_m(s)$ is known as the internal model of y_m and is designed to have all roots in $Re\{s\} \leq 0$ with no repeated roots on the $j\omega$-axis. The polynomial $A^*(s)$, referred to as the desired closed-loop characteristic polynomial, is chosen based on the closed-loop performance requirements. To meet the control objective, we make the following assumptions about the plant:

P1. $G_p(s)$ is strictly proper with known degree, and $R_p(s)$ is a monic polynomial whose degree n is known and $Q_m(s)Z_p(s)$ and $R_p(s)$ are coprime.

Assumption P1 allows Z_p and R_p to be non-Hurwitz in contrast to the MRAC case where Z_p is required to be Hurwitz.

The design of the APPC scheme is based on the CE principle. The plant parameters are estimated at each time t and used to calculate the controller parameters that meet the control objective for the estimated plant as follows: Using (6) the plant equation can be expressed in a form convenient for parameter estimation via the model (Goodwin and Sin 1984; Ioannou and Fidan 2006; Ioannou and Sun 1996):

$$z = \theta_p^* \phi,$$

where $z = \frac{s^n}{\Lambda_p(s)}y_p$, $\theta_p^* = [\theta_b^{*T}, \theta_a^{*T}]^T$, $\phi = [\frac{\alpha_{n-1}^T(s)}{\Lambda_p(s)}u_p, -\frac{\alpha_{n-1}^T(s)}{\Lambda_p(s)}y_p]^T$, $\alpha_{n-1} = [s^{n-1}, \ldots, s, 1]^T$, $\theta_a^* = [a_{n-1}, \ldots, a_0]^T$, $\theta_b^* = [b_{n-1}, \ldots, b_0]^T$, and $\Lambda_p(s)$ is a Hurwitz monic design polynomial. As an example of a parameter estimation algorithm, we consider the gradient algorithm

$$\dot{\theta}_p = \Gamma \varepsilon \phi, \quad \varepsilon = \frac{z - \theta_p^T \phi}{m_s^2}, \quad m_s^2 = 1 + \phi^T \phi, \qquad (7)$$

where $\Gamma = \Gamma^T > 0$ is the adaptive gain and $\theta_p = [\hat{b}_{n-1}, \ldots, \hat{b}_0, \hat{a}_{n-1}, \ldots, \hat{a}_0]^T$ are the estimated plant parameters which can be used to form the estimated plant polynomials $\hat{R}_p(s, t) = s^n + \hat{a}_{n-1}(t)s^{n-1} + \ldots + \hat{a}_1(t)s + \hat{a}_0(t)$ and $\hat{Z}_p(s, t) = \hat{b}_{n-1}(t)s^{n-1} + \ldots + \hat{b}_1(t)s + \hat{b}_0(t)$ of $R_p(s)$ and $Z_p(s)$, respectively, at each time t. The adaptive control law is given as

$$u_p = \left(\Lambda(s) - \hat{L}(s, t)Q_m(s) \right) \frac{1}{\Lambda(s)}u_p$$
$$- \hat{P}(s, t)\frac{1}{\Lambda(s)}(y_p - y_m), \qquad (8)$$

where $\hat{L}(s, t)$ and $\hat{P}(s, t)$ are obtained by solving the polynomial equation $\hat{L}(s, t) \cdot Q_m(s) \cdot \hat{R}_p(s, t) + \hat{P}(s, t) \cdot \hat{Z}_p(s, t) = A^*(s)$ at each time t. The operation $X(s, t) \cdot Y(s, t)$ denotes a multiplication of polynomials where s is simply treated as a variable. The existence and uniqueness of $\hat{L}(s, t)$ and $\hat{P}(s, t)$ is guaranteed provided $\hat{R}_p(s, t) \cdot Q_m(s)$ and $\hat{Z}_p(s, t)$ are coprime at each frozen time t. The adaptive laws that generate the coefficients of $\hat{R}_p(s, t)$ and $\hat{Z}_p(s, t)$ cannot guarantee this property, which means that at certain points in time, the solution $\hat{L}(s, t)$, $\hat{P}(s, t)$ may not exist. This problem is known as the stabilizability problem in indirect APPC and further modifications are needed in order to handle it (Goodwin and Sin 1984; Ioannou and Fidan 2006; Ioannou and Sun 1996). Assuming that the stabilizability condition holds at each time t, it can be shown (Goodwin and Sin 1984; Ioannou and Fidan 2006; Ioannou and Sun 1996) that all signals are bounded and the tracking error converges to zero with time. Other indirect adaptive pole placement control schemes include adaptive linear quadratic (Ioannou and Fidan 2006; Ioannou and Sun 1996). In principle any nonadaptive control scheme can be made adaptive by replacing the unknown parameters with their estimates in the calculation of the controller parameters. The design of direct APPC schemes is not possible in general as the map

between the plant and controller parameters is nonlinear, and the plant parameters cannot be expressed as a convenient function of the controller parameters. This prevents parametrization of the plant transfer function with respect to the controller parameters as done in the case of MRC. In special cases where such parametrization is possible such as in MRAC which can be viewed as a special case of APPC, the design of direct APPC is possible. Chapters on ▶ Adaptive Control, Overview, ▶ Robust Adaptive Control, and ▶ History of Adaptive Control provide additional information regarding MRAC and APPC.

Search Methods, Multiple Models, and Switching Schemes

One of the drawbacks of APPC is the stabilizability condition which requires the estimated plant at each time t to satisfy the detectability and stabilizability condition that is necessary for the controller parameters to exist. Since the adaptive law cannot guarantee such a property, an approach emerged that involves the pre-calculation of a set of controllers based on the partitioning of the plant parameter space. The problem then becomes one of identifying which one of the controllers is the most appropriate one. The switching to the "best" possible controller could be based on some logic that is driven by some cost index, multiple estimation models, and other techniques (Fekri et al. 2007; Hespanha et al. 2003; Kuipers and Ioannou 2010; Morse 1996; Narendra and Balakrishnan 1997; Stefanovic and Safonov 2011). One of the drawbacks of this approach is that it is difficult if at all possible to find a finite set of stabilizing controllers that cover the whole unknown parameter space especially for high-order plants. If found its dimension may be so large that makes it impractical. Another drawback that is present in all adaptive schemes is that in the absence of persistently exciting signals which guarantee that the input/output data have sufficient information about the unknown plant parameters, there is no guarantee that the controller the scheme converged to is indeed a stabilizing one. In other words, if switching is

disengaged or the adaptive law is switched off, there is no guarantee that a small disturbance will not drive the corresponding LTI scheme unstable. Nevertheless these techniques allow the incorporation of well-established robust control techniques in designing a priori the set of controller candidates. The problem is that if the plant parameters change in a way not accounted for a priori, no controller from the set may be stabilizing leading to an unstable system.

Robust Adaptive Control

The MRAC and APPC schemes presented above are designed for LTI systems. Due to the adaptive law, the closed-loop system is no longer LTI but nonlinear and time varying. It has been shown using simple examples that the pure integral action of the adaptive law could cause parameter drift in the presence of small disturbances and/or unmodeled dynamics (Ioannou and Fidan 2006; Ioannou and Kokotovic 1983; Ioannou and Sun 1996) which could then excite the unmodeled dynamics and lead to instability. Modifications to counteract these possible instabilities led to the field of robust adaptive control whose focus was to modify the adaptive law in order to guarantee robustness with respect to disturbances, unmodeled dynamics, time-varying parameters, classes of nonlinearities, etc., by using techniques such as normalizing signals, projection, fixed and switching sigma modification, etc.

Abstract

Adaptive control describes a range of techniques for altering control behavior using measured signals to achieve high control performance under uncertainty. The theory and practice of adaptive control has matured in many areas. This entry gives an overview of adaptive control with pointers to more detailed specific topics.

Keywords

Adaptive control; Estimation

Introduction

What Is Adaptive Control

Feedback control has a long history of using sensing, decision, and actuation elements to achieve an overall goal. The general structure of a control system may be illustrated in Fig. 1. It has long been known that high fidelity control relies on knowledge of the system to be controlled. For example, in most cases, knowledge of the plant gain and/or time constants (represented by θ_p in Fig. 1) is important in feedback control design. In addition, disturbance characteristics (e.g., frequency of a sinusoidal disturbance), θ_d in Fig. 1, are important in feedback compensator design.
Many control design and synthesis techniques are model based, using prior knowledge of both model structure and parameters. In other cases, a fixed controller structure is used, and the controller parameters, θ_C in Fig. 1, are tuned empirically during control system commissioning.

Adaptive Control, Overview, Fig. 1 General control and adaptive control diagram

However, if the plant parameters vary widely with time or have large uncertainties, these approaches may be inadequate for high-performance control.

There are two main ways of approaching high-performance control with unknown plant and disturbance characteristics:

1. Robust control (▶ Optimization Based Robust Control), wherein a controller is designed to perform adequately despite the uncertainties. Variable structure control may have very high levels of robustness in some cases and therefore is a special class of robust nonlinear control.

2. Adaptive control, where the controller learns and adjusts its strategy based on measured data. This frequently takes the form where the controller parameters, θ_C, are time-varying functions that depend on the available data ($y(t)$, $u(t)$, and $r(t)$). Adaptive control has close links to intelligent control (including neural control (▶ Neural Control and Approximate Dynamic Programming), where specific types of learning are considered) and also to stochastic adaptive control (▶ Stochastic Adaptive Control).

Robust control is most useful when there are large unmodeled dynamics (i.e., structural uncertainties), relatively high levels of noise, or rapid and unpredictable parameter changes. Conversely, for slow or largely predictable parameter variations, with relatively well-known model structure and limited noise levels, adaptive control may provide a very useful tool for high-performance control (Åström and Wittenmark 2008).

Varieties of Adaptive Control

One practical variant of adaptive control is controller auto-tuning (▶ Autotuning). Auto-tuning is particularly useful for PID and similar controllers and involves a specific phase of signal injection, followed by analysis, PID gain computation, and implementation. These techniques are an important aid to commissioning and maintenance of distributed control systems.

There are also large classes of adaptive controllers that are continuously monitoring the plant input-output signals to adjust the strategy. These adjustments are often parametrized by a relatively small number of coefficients, θ_C. These include schemes where the controller parameters are directly adjusted using measureable data (also referred to as "implicit," since there is no explicit plant model generated). Early examples of this often included model reference adaptive control (▶ Model Reference Adaptive Control). Other schemes (Middleton et al. 1988) explicitly estimate a plant model θ_P; thereafter, performing online control design and, therefore, the adaptation of controller parameters θ_C are indirect. This then led on to a range of other adaptive control techniques applicable to linear systems (▶ Adaptive Control of Linear Time-Invariant Systems).

There have been significant questions concerning the sensitivity of some adaptive control algorithms to unmodeled dynamics, time-varying systems, and noise (Ioannou and Kokotovic 1984; Rohrs et al. 1985). This prompted a very active period of research to analyze and redesign adaptive control to provide suitable robustness (▶ Robust Adaptive Control) (e.g., Anderson et al. 1986; Ioannou and Sun 2012) and parameter tracking for time-varying systems (e.g., Kreisselmeier 1986; Middleton and Goodwin 1988).

Work in this area further spread to nonparametric methods, such as switching, or supervisory adaptive control (▶ Switching Adaptive Control) (e.g., Fu and Barmish 1986; Morse et al. 1992). In addition, there has been a great deal of work on the more difficult problem of adaptive control for nonlinear systems (▶ Nonlinear Adaptive Control).

A further adaptive control technique is extremum seeking control (▶ Extremum Seeking Control). In extremum seeking (or self optimizing) control, the desired reference for the system is unknown, instead we wish to maximize (or minimize) some variable in the system (Ariyur and Krstic 2003). These techniques have quite distinct modes of operation that have proven important in a range of applications.

A final control algorithm that has nonparametric features is iterative learning control (▶ Iterative Learning Control) (Amann et al. 1996; Moore 1993). This control scheme considers a system with a highly structured, namely, repetitive finite run, control problem. In this case, by taking a nonparametric approach of utilizing information from previous run(s), in many cases, near-perfect asymptotic tracking can be achieved.

Adaptive control has a rich history (▶ History of Adaptive Control) and has been established as an important tool for some classes of control problems.

Adaptive Cruise Control

Rajesh Rajamani
Department of Mechanical Engineering,
University of Minnesota, Twin Cities,
Minneapolis, MN, USA

Abstract

This chapter discusses advanced cruise control automotive technologies, including adaptive cruise control (ACC) in which spacing control, speed control, and a number of transitional maneuvers must be performed. The ACC system must satisfy difficult performance requirements of vehicle stability and string stability. The technical challenges involved and the control design techniques utilized in ACC system design are presented.

Keywords

Collision avoidance; String stability; Traffic stability; Vehicle following

Introduction

Adaptive cruise control (ACC) is an extension of cruise control. An ACC vehicle includes a radar, a lidar, or other sensor that measures the distance to any preceding vehicle in the same lane on the highway. In the absence of preceding vehicles, the speed of the car is controlled to a driver-desired value. In the presence of a preceding vehicle, the controller determines whether the vehicle should switch from speed control to spacing control. In spacing control, the distance to the preceding car is controlled to a desired value.

A different form of advanced cruise control is a *forward collision avoidance* (FCA) system. An FCA system uses a distance sensor to determine if the vehicle is approaching a car ahead too quickly and will automatically apply brakes to minimize the chances of a forward collision. For the 2013 model year, 29 % vehicles have forward collision warning as an available option and 12 % include autonomous braking for a full FCA system. Examples of models in which an FCA system is standard are the Mercedes Benz G-class and the Volvo S-60, S-80, XC-60, and XC-70.

It should be noted that an FCA system does not involve steady-state vehicle following. An ACC system on the other hand involves control of speed and spacing to desired steady-state values.

ACC systems have been in the market in Japan since 1995, in Europe since 1998, and in the US since 2000. An ACC system provides enhanced driver comfort and convenience by allowing extended operation of the cruise control option even in the presence of other traffic.

Controller Architecture

The ACC system has two modes of steady state operation: speed control and vehicle following (i.e., spacing control). Speed control is traditional cruise control and is a well-established technology. A proportional-integral controller based on feedback of vehicle speed (calculated from rotational wheel speeds) is used in cruise control (Rajamani 2012).
Adaptive Cruise Control, Fig. 1 Structure of longitudinal control system

Controller design for vehicle following is the primary topic of discussion in the sections titled "Vehicle Following Requirements" and "String Stability Analysis" in this chapter.

Transitional maneuvers and transitional control algorithms are discussed in the section titled "Transitional Maneuvers" in this chapter.

The longitudinal control system architecture for an ACC vehicle is typically designed to be hierarchical, with an upper-level controller and a lower-level controller, as shown in Fig. 1.

The upper-level controller determines the desired acceleration for the vehicle. The lower level controller determines the throttle and/or brake commands required to track the desired acceleration. Vehicle dynamic models, engine maps, and nonlinear control synthesis techniques are used in the design of the lower controller (Rajamani 2012). This chapter will focus only on the design of the upper controller, also known as the ACC controller.

As far as the upper-level controller is concerned, the plant model for control design is

$$\ddot{x}_i = u \tag{1}$$

where the subscript i denotes the ith car in a string of consecutive ACC cars. The acceleration of the car is thus assumed to be the control input. However, due to the finite bandwidth associated

Adaptive Cruise Control,
Fig. 2 String of adaptive
cruise control vehicles
with the lower level controller, each car is actually expected to track its desired acceleration imperfectly. The objective of the upper level controller design is therefore stated as that of meeting required performance specifications robustly in the presence of a first order lag in the lower-level controller performance:

$$\ddot{x}_i = \frac{1}{\tau s + 1}\ddot{x}_{i\_\text{des}} = \frac{1}{\tau s + 1}u_i. \qquad (2)$$

Equation (1) is thus assumed to be the nominal plant model while the performance specifications have to be met even if the actual plant model were given by Eq. (2). The lag τ typically has a value between 0.2 and 0.5 s (Rajamani 2012).

Vehicle Following Requirements

In the vehicle following mode of operation, the ACC vehicle maintains a desired spacing from the preceding vehicle. The two important performance specifications that the vehicle following control system must satisfy are: individual vehicle stability and string stability.

(a) **Individual vehicle stability**
Consider a string of vehicles on the highway using a longitudinal control system for vehicle following, as shown in Fig. 2. Let x_i be the location of the ith vehicle measured from an inertial reference. The spacing error for the ith vehicle (the ACC vehicle under consideration) is then defined as

$$\delta_i = x_i - x_{i-1} + L_\text{des}. \qquad (3)$$

Here, L_des is the desired spacing and includes the preceding vehicle length ℓ_{i-1}. L_des could be chosen as a function of variables such as the

vehicle speed $\dot{x}_i$. The ACC control law is said to provide individual vehicle stability if the spacing error of the ACC vehicle converges to zero when the preceding vehicle is operating at constant speed:

$$\ddot{x}_{i-1} \to 0 \Rightarrow \delta_i \to 0. \qquad (4)$$

(b) **String stability**
The spacing error is expected to be non-zero during acceleration or deceleration of the preceding vehicle. It is important then to describe how the spacing error would propagate from vehicle to vehicle in a string of ACC vehicles during acceleration. The string stability of a string of ACC vehicles refers to a property in which spacing errors are guaranteed not to amplify as they propagate towards the tail of the string (Swaroop and Hedrick 1996).

String Stability Analysis

In this section, mathematical conditions that ensure string stability are provided.

Let δ_i and δ_{i-1} be the spacing errors of consecutive ACC vehicles in a string. Let $\hat{H}(s)$ be the transfer function relating these errors:

$$\hat{H}(s) = \frac{\hat{\delta}_i}{\hat{\delta}_{i-1}}(s). \qquad (5)$$

The following two conditions can be used to determine if the system is string stable:
(a) The transfer function $\hat{H}(s)$ should satisfy

$$\left\| \hat{H}(s) \right\|_\infty \le 1. \qquad (6)$$

(b) The impulse response function $h(t)$ corresponding to $\hat{H}(s)$ should not change sign (Swaroop and Hedrick 1996), i.e.,

$$h(t) > 0 \quad \forall t \geq 0. \tag{7}$$

The reasons for these two requirements to be satisfied are described in Rajamani (2012). Roughly speaking, Eq. (6) ensures that $||\delta_i||_2 \leq ||\delta_{i-1}||_2$, which means that the energy in the spacing error signal decreases as the spacing error propagates towards the tail of the string. Equation (7) ensures that the steady state spacing errors of the vehicles in the string have the same sign. This is important because a positive spacing error implies that a vehicle is closer than desired while a negative spacing error implies that it is further apart than desired. If the steady state value of δ_i is positive while that of δ_{i-1} is negative, then this might be dangerous due to the vehicle being closer, even though in terms of magnitude δ_i might be smaller than δ_{i-1}.

If conditions (6) and (7) are both satisfied, then $||\delta_i||_\infty \leq ||\delta_{i-1}||_\infty$ (Rajamani 2012).

Constant Inter-vehicle Spacing

The ACC system only utilizes on board sensors like radar and does not depend on inter-vehicle communication from other vehicles. Hence the only variables available as feedback for the upper controller are inter-vehicle spacing, relative velocity and the ACC vehicle's own velocity.

Under the constant spacing policy, the spacing error of the ith vehicle was defined in Eq. (3).

If the acceleration of the vehicle can be instantaneously controlled, then it can be shown that a linear control system of the type

$$\ddot{x}_i = -k_p \delta_i - k_v \dot{\delta}_i \tag{8}$$

results in the following closed-loop transfer function between consecutive spacing errors

$$\hat{H}(s) = \frac{\hat{\delta}_i}{\hat{\delta}_{i-1}}(s) = \frac{k_p + k_v s}{s^2 + k_v s + k_p}. \tag{9}$$

Equation (9) describes the propagation of spacing errors along the vehicle string.

All positive values of k_p and k_v guarantee individual vehicle stability. However, it can be shown that there are no positive values of k_p and k_v for which the magnitude of $G(s)$ can be guaranteed to be less than unity at all frequencies. The details of this proof are available in Rajamani (2012).

Thus, the constant spacing policy will always be string unstable.

Constant Time-Gap Spacing

Since the constant spacing policy is unsuitable for autonomous control, a better spacing policy that can ensure both individual vehicle stability and string stability must be used. The constant time-gap (CTG) spacing policy is such a spacing policy. In the CTG spacing policy, the desired inter-vehicle spacing is not constant but varies with velocity. The spacing error is defined as

$$\delta_i = x_i - x_{i-1} + L_{\text{des}} + h\dot{x}_i. \tag{10}$$

The parameter h is referred to as the time-gap.

The following controller based on the CTG spacing policy can be used to regulate the spacing error at zero (Swaroop et al. 1994):

$$\ddot{x}_{i\_\text{des}} = -\frac{1}{h}(\dot{x}_i - \dot{x}_{i-1} + \lambda \delta_i) \tag{11}$$

With this control law, it can be shown that the spacing errors of successive vehicles δ_i and δ_{i-1} are independent of each other:

$$\dot{\delta}_i = -\lambda \delta_i \tag{12}$$

Thus, δ_i is independent of δ_{i-1} and is expected to converge to zero as long as $\lambda > 0$. However, this result is only true if any desired acceleration can be instantaneously obtained by the vehicle i.e., if $\tau = 0$.

In the presence of the lower controller and actuator dynamics given by Eq. (2), it can be shown that the dynamic relation between δ_i and δ_{i-1} in the transfer function domain is

$$\hat{H}(s) = \frac{s + \lambda}{h\tau s^3 + hs^2 + (1 + \lambda h)s + \lambda} \quad (13)$$

The string stability of this system can be analyzed by checking if the magnitude of the above transfer function is always less than or equal to 1. It can be shown that this is the case at all frequencies if and only if (Rajamani 2012)

$$h \geq 2\tau. \quad (14)$$

Further, if Eq. (14) is satisfied, then it is also guaranteed that one can find a value of λ such that Eq. (7) is satisfied. Thus the condition (14) is necessary (Swaroop and Hedrick 1996) for string stability.

Since the typical value of τ is of the order of 0.5 s, Eq. (14) implies that ACC vehicles must maintain at least a 1-s time gap between vehicles for string stability.

Transitional Maneuvers

While under speed control, an ACC vehicle might suddenly encounter a new vehicle in its lane (either due to a lane change or due to a slower moving preceding vehicle). The ACC vehicle must then decide whether to continue to operate under the speed control mode or transition to the vehicle following mode or initiate hard braking. If a transition to vehicle following is required, a transitional trajectory that will bring the ACC vehicle to its steady state following distance needs to be designed. Similarly, a decision on the mode of operation and design of a transitional trajectory are required when an ACC vehicle loses its target.

The regular CTG control law cannot directly be used to follow a newly encountered vehicle, see Rajamani (2012) for illustrative examples.

When a new target vehicle is encountered by the ACC vehicle, a "range – range rate" diagram can be used (Fancher and Bareket 1994) to decide if

(a) The vehicle should use speed control.
(b) The vehicle should use spacing control (with a defined transition trajectory in which desired spacing varies slowly with time)
(c) The vehicle should brake as hard as possible in order to avoid a crash.

The maximum allowable values for acceleration and deceleration need to be taken into account in making these decisions.

For the range – range rate $(R - \dot{R})$ diagram, define range R and range rate $\dot{R}$ as
$$R = x_{i-1} - x_i \quad (15)$$

$$\dot{R} = \dot{x}_{i-1} - \dot{x}_i = V_{i-1} - V_i \quad (16)$$

where x_{i-1}, x_i, V_{i-1}, and V_i are inertial positions and velocities of the preceding vehicle and the ACC vehicle respectively.

A typical $R - \dot{R}$ diagram is shown in Fig. 3 (Fancher and Bareket 1994). Depending on the

Adaptive Cruise Control,
Fig. 3 Range vs. range-rate diagram

Adaptive Cruise Control, Fig. 4 Switching line for spacing control

measured real-time values of R and $\dot{R}$, and the $R - \dot{R}$ diagram in Fig. 3, the ACC system determines the mode of longitudinal control. For instance, in region 1, the vehicle continues to operate under speed control. In region 2, the vehicle operates under spacing control. In region 3, the vehicle decelerates at the maximum allowed deceleration so as to try and avoid a crash.

The switching line from speed to spacing control is given by

$$R = -T\dot{R} + R_{\text{final}} \qquad (17)$$

where T is the slope of the switching line. When a slower vehicle is encountered at a distance larger than the desired final distance R_{final}, the switching line shown in Fig. 4 can be used to determine when and whether the vehicle should switch to spacing control. If the distance R is greater than that given by the line, speed control should be used.

The overall strategy (shown by trajectory ABC) is to first reduce gap at constant $\dot{R}$ and then follow the desired spacing given by the switching line of Eq. (17).

The control law during spacing control on this transitional trajectory is as follows. Depending on the value of $\dot{R}$, determine R from Eq. (17). Then use R as the desired inter-vehicle spacing in the PD control law

$$\ddot{x}_{\text{des}} = -k_p \left(x_i - R\right) - k_d \left(\dot{x}_i - \dot{R}\right) \qquad (18)$$

The trajectory of the ACC vehicle during constant deceleration is a parabola on the $R - \dot{R}$ diagram (Rajamani 2012).

The switching line should be such that travel along the line is comfortable and does not constitute high deceleration. The deceleration during coasting (zero throttle and zero braking) can be used to determine the slope of the switching line (Rajamani 2012).

Note that string stability is not a concern during transitional maneuvers (Rajamani 2012).

Traffic Stability

In addition to individual vehicle stability and string stability, another type of stability analysis that has received significant interest in ACC literature is traffic flow stability. Traffic flow stability refers to the stable evolution of traffic velocity and traffic density on a highway section, for given inflow and outflow conditions. One well-known result in this regard in literature is that traffic flow is defined to be stable if $\frac{\partial q}{\partial \rho}$ is positive, i.e., as the density ρ of traffic increases, traffic flow rate q must increase (Swaroop and Rajagopal 1999). If this condition is not satisfied, the highway section would be unable to accommodate any constant inflow of vehicles from an oncoming ramp. The steady state traffic flow on the highway section would come to a stop, if the ramp inflow did not stop (Swaroop and Rajagopal 1999).

It has been shown that the constant time-gap spacing policy used in ACC systems has a negative $q - \rho$ slope and thus does not lead to traffic flow stability (Swaroop and Rajagopal 1999). It has also been shown that it is possible to design other spacing policies (in which the desired spacing between vehicles is a nonlinear function of speed, instead of being proportional to speed) that can provide stable traffic flow (Santhanakrishnan and Rajamani 2003).

The importance of traffic flow stability has not been fully understood by the research community. Traffic flow stability is likely to become important when the number of ACC vehicles

on the highway increase and their penetration percentage into vehicles on the road becomes significant.

Recent Automotive Market Developments

The latest versions of ACC systems on the market have been enhanced with collision warning, integrated brake support, and stop-and-go operation functionality.

The collision warning feature uses the same radar as the ACC system to detect moving vehicles ahead and determine whether driver intervention is required. In this case, visual and audio warnings are provided to alert the driver and brakes are pre-charged to allow quick deceleration. On Ford's ACC-equipped vehicles, brakes are also automatically applied when the driver lifts the foot off from the accelerator pedal in a detected collision warning scenario.

When enabled with stop-and-go functionality, the ACC system can also operate at low vehicle speeds in heavy traffic. The vehicle can be automatically brought to a complete stop when needed and restarted automatically. Stop-and-go is an expensive option and requires the use of multiple radar sensors on each car. For instance, the BMW ACC system uses two short range and one long range radar sensor for stop-and-go operation.

The 2013 versions of ACC on the Cadillac ATS and on the Mercedes Distronic systems are also being integrated with camera based lateral lane position measurement systems. On the Mercedes Distronic systems, a camera steering assist system provides automatic steering, while on the Cadillac ATS, a camera based system provides lane departure warnings.

Future Directions

Current ACC systems use only on-board sensors and do not use wireless communication with other vehicles. There is a likelihood of evolution of current systems into co-operative adaptive cruise control (CACC) systems which utilize wireless communication with other vehicles and highway infrastructure. This evolution could be facilitated by the dedicated short-range communications (DSRC) capability being developed by government agencies in the US, Europe and Japan. In the US, DSRC is being developed with a primary goal of enabling communication between vehicles and with infrastructure to reduce collisions and support other safety applications. In CACC, wireless communication could provide acceleration signals from several preceding downstream vehicles. These signals could be used in better spacing policies and control algorithms to improve safety, ensure string stability, and improve traffic flow.

Advanced Manipulation for Underwater Sampling

Giuseppe Casalino
University of Genoa, Genoa, Italy

Abstract

This entry deals with the kinematic self-coordination aspects to be managed by parts of underwater floating manipulators, whenever employed for sample collections at the seafloor.

Kinematic self-coordination is here intended as the autonomous ability exhibited by the system in closed loop specifying the most appropriate reference velocities for its main constitutive parts (i.e., the supporting vehicle and the arm) in order to execute the sample collection with respect to both safety and best operability conditions for the system while also guaranteeing the needed "execution agility" in performing the task, particularly useful in case of underwater repeated collections. To this end, the devising and employment of a unifying control framework capable of guaranteeing the above properties will be outlined.

Such a framework is however intended to only represent the so-called Kinematic Control Layer (KCL) overlaying a Dynamic Control Layer (DCL), where the overall system dynamic and hydrodynamic effects are suitably accounted for, to the benefit of closed loop tracking of the reference system velocities. Since the DCL design is carried out in a way which is substantially independent from the system mission(s), it will not constitute a specific topic of this entry, even if some orienting references about it will be provided.

At this entry's end, as a follow-up of the resulting structural invariance of the devised KCL framework, future challenges addressing much wider and complex underwater applications will be foreseen, beyond the here-considered sample collection one.

Keywords

Introduction

An automated system for underwater sampling is here intended to be an autonomous underwater floating manipulator (see Fig. 1) capable of collecting samples corresponding to an a priori assigned template. The snapshots of Fig. 1 outline the most recent realization of a system of this kind (completed in 2012 within the EU-funded project TRIDENT; Sanz et al. 2012) when in operation, which is characterized by a vehicle and an endowed 7-dof arm exhibiting comparable masses and inertia, thus resulting in potentially faster and more agile designs than the very few similar previous realizations.

Its general the operational mode consists in exploring an assigned area of the seafloor, while executing a collection each time a feature corresponding to the assigned template is recognized (by the vehicle endowed with a stereovision system) as a sample to be collected.

Thus the autonomous functionalities to be exhibited are the following (to be sequenced as they are listed on an event-driven basis): (1) explore an assigned seabed area while visually performing model-based sample recognitions, (2) suspend the exploration and grasping a recognized sample, (3) deposit the sample inside an endowed container, and (4) then restart exploring till the next recognized sample.

Functionalities (1) and (4), since they do not require the arm usage, naturally reenter within the topics of navigation, patrolling, visual mapping, etc., which are typical of traditional AUVs and consequently will not be discussed here. Only functionality (2) will be discussed, since it is most distinctive of the considered system (often termed as I-AUV, with "I" for "Intervention") and because functionality (3) can be established along the same lines of (2) as a particular simpler case.
Advanced Manipulation for Underwater Sampling, Fig. 1 Snapshots showing the underwater floating manipulator TRIDENT when autonomously picking an identified object

By then focusing on functionality (2), we must note how the sample grasping ultimate objective, which translates into a specific position/attitude to be reached by the end-effector, must however be achieved within the preliminary fulfillment of also other objectives, each one reflecting the need of guaranteeing the system operating within both its safety and best operability conditions. For instance, the arm's joint limits must be respected and the arm singular postures avoided. Moreover, since the sample position is estimated via the vehicle with a stereo camera, the sample must stay grossly centered inside its visual cone, since otherwise the visual feedback would be lost and the sample search would need to start again. Also, the sample must stay within suitable horizontal and vertical distance limits from the camera frame, in order for the vision algorithm to be well performing. And furthermore, in these conditions the vehicle should be maintained with an approximately horizontal attitude, for energy savings.

With the exception of the objective of making the end-effector position/attitude reaching the grasping position, which is clearly an equality condition, its related safety/enabling objectives are instead represented by a set of inequality conditions (involving various system variables) whose achievement (accordingly with their safety/enabling role) must therefore deserve the highest priority.

System motions guaranteeing such prioritized objective achievements should moreover allow for a concurrent management of them (i.e., avoiding a sequential motion management whenever possible), which means requiring each objective progressing toward its achievement, by at each time instant only exploiting the residual system mobility allowed by the current progresses of its higher priority objectives. Since the available system mobility will progressively increase during time, accordingly with the progressive achievement of all inequality objectives, this will guarantee the grasping objective to be also completed by eventually progressing within adequate system safety and best operability conditions. In this way the system will also exhibit the necessary "agility" in executing its maneuvers, in a way faster than in case they were executed on a sequential motion basis.

The devising of an effective way to incorporate all the inequality and equality objectives within a uniform and computationally efficient task-priority-based algorithmic framework for underwater floating manipulators has been the

result of the developments outlined in the next section.

The developed framework however solely represents the so-called Kinematic Control Layer (KCL) of the overall control architecture, that is, the one in charge of closed-loop real-time control generating the system velocity vector y as a reference signal, to be in turn concurrently tracked, via the action of the arm joint torques and vehicle thrusters, by an adequate underlying Dynamic Control Layer (DCL), where the overall dynamic and hydrodynamic effects are kept into account to the benefit of such velocity tracking. Since the DCL can actually be designed in a way substantially independent from the system mission(s), it will not constitute a specific topic of this entry. Its detailed dynamic-hydrodynamic model-based structuring, also including a stability analysis, can be found in Casalino (2011), together with a more detailed description of the upper-lying KCL, while more general references on underwater dynamic control aspects can be found, for instance, in Antonelli (2006).

Task-Priority-Based Control of Floating Manipulators

The above-outlined typical set of objectives (of inequality and/or equality types) to be achieved within a sampling mission are here formalized. Then some helpful generalizing definitions are given, prior to presenting the related unifying task-priority-based algorithmic framework to be used.

Inequality and Equality Objectives

One of the objectives, of inequality type, related to both arm safety and its operability is that of maintaining each joint within corresponding minimum and maximum limits, that is,

$$q_{1m} < q_i < q_{iM}; \quad i = 1, 2, \ldots, 7$$

Moreover, in order to have the arm operating with dexterity, its manipulability measure (Nakamura 1991; Yoshikawa 1985) must ultimately stay above a minimum threshold value, thus also

requiring the achievement of the inequality type objective

$$\mu > \mu_m$$

While the above objectives arise from inherently scalar variables, other objectives instead arise as conditions to be achieved within the Cartesian space, where each one of them can be conveniently expressed in terms of the modulus associated to a corresponding Cartesian vector variable.

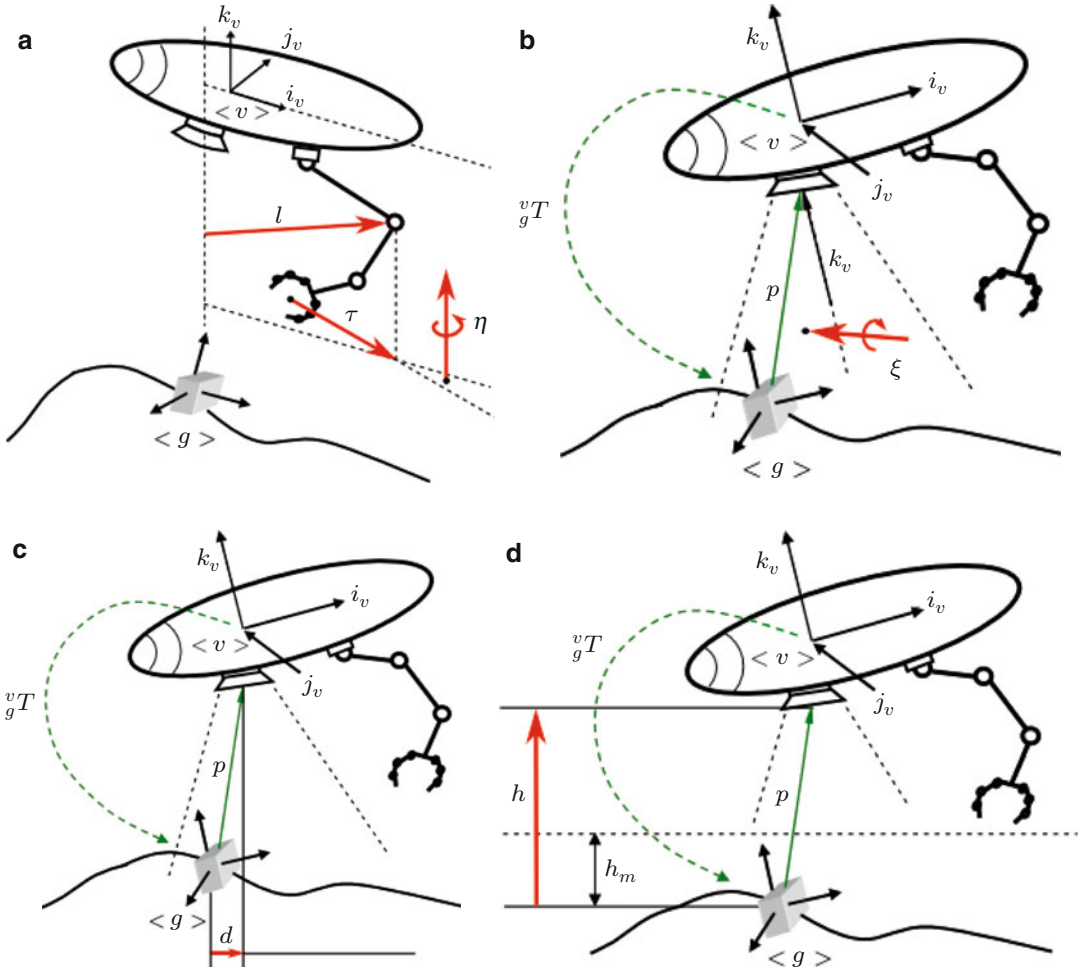
To be more specific, let us, for instance, refer to the need of avoiding the occlusions between the sample and the stereo camera, which might occasionally occur due to the arm link motions. Then such need can be, for instance, translated into the ultimate achievement of the following set of inequalities, for suitable chosen values of the boundaries

$$\|l\| > l_m; \quad \|\tau\| > \tau_m; \quad \|\eta\| < \eta_M$$

where l is the vector lying on the vehicle x-y plane, joining the arm elbow with the line parallel to the vehicle z-axis and passing through camera frame origin, as sketched in Fig. 2a. Moreover η is the misalignment vector formed by vector τ also lying on the vehicle x-y plane, joining the lines parallel to the vehicle z-axis and, respectively, passing through the elbow and the end-effector origin.

As for the vehicle, it must keep the object of interest grossly centered in the camera frame (see Fig. 2b), thus meaning that the modulus of the orientation error ξ, formed by the unit vector n_p of vector p from the sample to the camera frame and the unit vector k_c of the z-axis of the camera frame itself, must ultimately satisfy the inequality

$$\|\xi\| < \xi_M$$

Furthermore, the camera must also be closer than a given horizontal distance d_M to the vertical line passing through the sample, and it must lie between a maximum and minimum height with respect to the sample itself, thus implying the achievement of the following inequalities (Fig. 2c, d):


Advanced Manipulation for Underwater Sampling, Fig. 2 Vectors allowing for the defintion of some inequality objectives in the Cartesian space: (*a*) camera occlusion, (*b*) camera centering, (*c*) camera distance, (*d*) camera height

$$\|d\| < d_M; \quad h_m < \|h\| < h_M$$

Also since the vehicle should exhibit an almost horizontal attitude, this further requires the achievement of the following additional inequality:

$$\|\phi\| < \phi_M$$

with ϕ the misalignment vector formed by the absolute vertical unit vector k_o with the vehicle z-axis one k_v.

And finally the end-effector must eventually reach the sample, for then picking it. Thus the following, now of equality type, objectives must also be ultimately achieved, where r is the position error and θ the orientation one of the end-effector frame with respect to the sample frame

$$\|r\| = 0; \quad \|\vartheta\| = 0$$

As already repeatedly remarked, the achievement of the above inequality objectives (since related to the system safety and/or its best operability) must globally deserve a priority higher than the last equality.

Basic Definitions

The following definitions only regard a generic vector $s \in R^3$ characterizing a corresponding generic objective defined in the Cartesian space

(for instance, with the exclusion of the joint and manipulability limits, all the other above-reported objectives). In this case the vector is termed to be the error vector of the objective, and it is assumed measured with components on the vehicle frame. Then its modulus

$$\sigma \doteq \|s\|$$

is termed to be the error, while its unit vector

$$n \doteq s/\sigma; \quad \sigma \neq 0$$

is accordingly denoted as the unit error vector. Then the following differential Jacobian relationship can always be evaluated for each of them:

$$\dot{s} = Hy$$

where $y \in R^N$ ($N = (7 + 6)$ for the system of Fig. 1) is the stacked vector composed of the joint velocity vector $\dot{q} \in R^7$, plus the stacked vector $v \in R^6$ of the absolute vehicle velocities (linear and angular) with components on the vehicle frame and with $\dot{s}$ clearly representing the time derivative of vector s itself, as seen from the vehicle frame and with components on it (see Casalino (2011) for details on the real-time evaluation of Jacobian matrices H).

Obviously, for the time derivative $\dot{\sigma}$ of the error, also the following differential relationship holds

$$\dot{\sigma} = n^T Hy$$

Further, to each error variable σ, a so-called error reference rate is real time assigned of the form

$$\dot{\bar{\sigma}} = -\gamma(\sigma - \sigma^o)\alpha(\sigma)$$

where for equality objectives σ^o is the target value and $\alpha(\sigma) \equiv 1$, while for inequality ones, σ^o is the threshold value and $\alpha(\sigma)$ is a left-cutting or right-cutting (in correspondence of σ^o) smooth sigmoidal activation function, depending on whether the objective is to force σ to be below or above σ^o, respectively.

In case $\dot{\bar{\sigma}}$ could be exactly assigned to its corresponding error rate $\dot{\sigma}$, it would consequently smoothly drive σ toward the achievement of its associated objective. Note however that for inequality objectives, it would necessarily impose $\dot{\sigma} = 0$ in correspondence of a point located inside the interval of validity of the inequality objective itself, while instead such an error rate zeroing effect should be relaxed, for allowing the helpful subsequent system mobility increase, which allows for further progress toward other lower priority control objectives. Such a relaxation aspect will be dealt with soon.

Furthermore, in correspondence of a reference error rate $\dot{\bar{\sigma}}$, the so-called reference error vector rate can also be defined as

$$\dot{\bar{s}} \doteq n\dot{\bar{\sigma}}$$

that for equality objectives requiring the zeroing of their error σ simply becomes

$$\dot{\bar{s}} \doteq -\gamma s$$

whose evaluation, since not requiring its unit vector n, will be useful for managing equality objectives.

Finally note that for each objective not defined in the Cartesian space (like, for instance, the above joint limits and manipulability), the corresponding scalar error variable, its rate, and its reference error rate can instead be managed directly, since obviously they do not require any preliminary scalar reduction process.

Managing the Higher Priority Inequality Objectives

A prioritized list of the various scalar inequality objectives, to be concurrently progressively achieved, is suitably established in a descending priority order.

Then, by starting to consider the highest priority one, we have that the linear manifold of the system velocity vector y (i.e., the arm joints velocity vector $\dot{q}$ stacked with vector v of the vehicle linear and angular velocities), capable of driving toward its achievement, results at each

time instant as the set of solution of the following minimization problem with scalar argument, with row vector $G_1 \doteq \alpha_1 n_1^T H_1$ and scalar α_1 the same activation function embedded within the reference error rate $\dot{\bar{\sigma}}_1$

$$
S_1 \doteq \left\{ \underset{y}{\mathrm{argmin}} \left\| \dot{\bar{\sigma}}_1 - G_1 y \right\|^2 \right\} \quad \Leftrightarrow
$$
$$
y = G_1^{\#} \dot{\bar{\sigma}}_1 + (I - G_1^{\#} G_1) z_1 \doteq \rho_1 + Q_1 z_1; \ \forall z_1
$$
$$(1)$$

The above minimization, whose solution manifold appears at the right (also expressed in a concise notation with an obvious correspondence of terms) parameterized by the arbitrary vector z_1, has to be assumed executed without extracting the common factor α_1, that is, by evaluating the pseudo-inverse matrix $G_1^{\#}$ via the regularized form

$$
G_1^{\#} = \left(\alpha_1^2 n_1^T H_1 H_1^T n_1 + p_1 \right)^{-1} \alpha_1 H_1^T n_1
$$

with p_1, a suitably chosen bell-shaped, finite support and centered on zero, regularizing function of the norm of row vector G_1.

In the above solution manifold, when $\alpha_1 = 1$ (i.e., when the first inequality is still far to be achieved), the second arbitrary term $Q_1 z_1$ is orthogonal to the first, thus having no influence on the generated $\dot{\sigma}_1 = \dot{\bar{\sigma}}_1$ and consequently suitable to be used for also progressing toward the achievement of other lower priority objectives, without perturbing the current progressive achievement of the first one. Note however that, since in this condition the span of the second term results one dimension less than the whole system velocity space $y \in R^N$, this implies that the lower priority objectives can be progressed by only acting within a one-dimension reduced system velocity subspace.

When $\alpha_1 = 0$ (i.e., when the first inequality is achieved) since $G_1^{\#} = 0$ (as granted by the regularization) and consequently $y = z_1$, the lower priority objectives can instead be progressed by now exploiting the whole system velocity space.

When instead α_1 is within its transition zone $0 < \alpha_1 < 1$ (i.e., when the first inequality is near to be achieved), since the two terms of the solution manifold now become only approximately orthogonal, this can make the usage of the second term for managing lower priority tasks, possibly counteracting the first, currently acting in favor of the highest priority one, but in any case without any possibility of making the primary error variable σ_1 getting out of its enlarged boundaries (i.e., the ones inclusive of the transition zone), thus meaning that once the primary variable σ_1 has entered within such larger boundaries, it will definitely never get out of them.

With the above considerations in mind, managing the remaining priority-descending sequence of inequality objectives can then be done by applying the same philosophy to each of them and within the mobility space left free by its preceding ones, that is, as the result of the following sequence of nested minimization problems:

$$
S_i \doteq \left\{ \underset{y \in S_{i-1}}{\mathrm{argmin}} \left\| \dot{\bar{\sigma}}_i - G_i y \right\|^2 \right\}; \quad i = 1, 2, \ldots, k
$$

with $G_i \doteq \alpha_i n_i^T H_i$ and with k indexing the lowest priority inequality objective and where the highest priority objective has been also included for the sake of completeness (upon letting $S_o = R^N$). In this way the procedure guarantees the concurrent prioritized convergence (actually occurring as a sort of "domino effect" scattering along the prioritized objective list) toward the ultimate fulfillment of all inequality objectives, each one within its enlarged bounds at worse and with no possibility of getting out of them, once reached.

Further, a simple algebra allows translating the above sequence of k nested minimizations into the following algorithmic structure, with initialization $\rho_0 = 0$; $Q_0 = I$ (see Casalino et al. 2012a,b for more details):

$$
\hat{G}_1 \doteq G_i Q_i
$$
$$
T_i = \left(I - Q_{i-1} G_i^{\#} G_i \right)
$$

$$\rho_i = T_i \rho_{i-1} + Q_{i-1} G_i^{\#} \dot{\sigma}_i$$

$$Q_i = Q_{i-1} \left(I - G_i^{\#} G_i \right)$$

ending with the last k-th iteration with the solution manifold

$$y = \rho_k + Q_k z_k; \quad \forall z_k$$

where the residual arbitrariness space $Q_k z_z$ has to be then used for managing the remaining equality objectives, as hereafter indicated.

Managing the Lower Priority Equality Objectives and Subsystem Motion Priorities

For managing the lower priority equality objectives when these require the zeroing of their associated error σ_i (as, for instance, for the end-effector sample reaching task), the following sequence of nested minimization problems has to be instead considered (with initialization ρ_k; Q_k):

$$S_i \doteq \left\{ \underset{y \in S_{i-1}}{\operatorname{argmin}} \left\| \dot{\bar{s}}_i - H_i y \right\|^2 \right\}; \ i = (k+1), \ldots, m$$

with m indexing the last priority equality objective and where the whole reference error vector rates $\dot{\bar{s}}_i$ and associated whole error vectors $\dot{s}_i$ have now to be used, since for $\alpha_i \equiv 1$ (as it is for any equality objective) the otherwise needed evaluation of unit vectors n_i (which become ill defined for the relevant error σ_i approaching zero) would most probably provoke unwanted chattering phenomena around $\sigma_i = 0$, while instead the above avoids such risk (since $\dot{\bar{s}}_i$ and $\dot{s}_i$ can be evaluated without requiring n_i), even if at the cost of requiring, for each equality objective, three degrees of mobility instead of a sole one, as it instead is for each inequality objectives. However, note how the algorithmic translation of the above procedure remains structurally the same as the one for the inequality objectives (obviously with the substitutions $\dot{\bar{s}}_i \rightarrow \dot{\sigma}_i$, $H_i \rightarrow G_i$, and with initialization ρ_k, Q_k), thus ending in correspondence of the m-th last equality objective with the solution manifold

$$y = \rho_m + Q_m z_m; \quad \forall z_m$$

where the still possibly existing residual arbitrariness space $Q_m z_m$ can be further used for assigning motion priorities between the arm and the vehicle, for instance, via the following additional least-priority ending task

$$y = \underset{y \in S_m}{\operatorname{argmin}} \| v \|^2 = \rho_{m+1}$$

whose solution ρ_{m+1} (with no more arbitrariness required) finally assures (while respecting all previous priorities) a motion minimality of the vehicle, thus implicitly assigning to the arm a greater mobility, which in turn allows the exploitation of its generally higher motion precision, especially during the ultimate convergence toward the final grasping.

Implementations

The recently realized TRIDENT system of Fig. 1, embedding the above introduced task-priority-based control architecture, has been operating at sea in 2012 (Port Soller Harbor, Mallorca, Spain). A detailed presentation of the preliminary performed simulations, then followed by pool experiments, and finally followed by field trials executed within a true underwater sea environment can be found in Simetti et al. (2013). The related EU-funded TRIDENT project (Sanz et al. 2012) is the first one where agile manipulation could be effectively achieved by part of an underwater floating manipulator, not only as the consequence of the comparable masses and inertia exhibited by the vehicle and arm, but mainly due to the adopted unified task-priority-based control framework. Capabilities for autonomous underwater floating manipulation were however already achieved for the first time in 2009 at the University of Hawaii, within the SAUVIM project (Marani et al. 2009, 2014; Yuh et al. 1998) even if without effective agility (the related system was in fact a 6-t vehicle endowed with a less than 35 kg arm).

Future Directions

The presented task-priority-based KCL structure is invariant with the addition, deletion, and substitution (even on-the-fly) of the various objectives, as well as invariant to changes in their priority ordering, thus constituting an invariant core potentially capable of supporting intervention tasks beyond the sole sample collection ones. On this basis, more complex systems and operational cases, such as, for instance, multi-arm systems and/or even cooperating ones, can be foreseen to be developed along the lines established by the roadmap of Fig. 3 (with case 0 the current development state).

The future availability of agile floating single-arm or multi-arm manipulators, also implementing cooperative interventions in force of a unified control and coordination structure (to this aim purposely extended), might in fact pave the way toward the realization of underwater hard-work robotized places, where different intervention agents might individually or cooperatively perform different object manipulation and transportation activities, also including assembly ones, thus far beyond the here considered case of sample collection. Such scenarios deserve the attention not only of the science community when needing to execute underwater works (excavation, coring, instrument handling, etc.,

other than sample collection) at increasing depths but obviously also those of the offshore industry.

Moreover, by exploiting the current and future developments on underwater exploration and survey mission performed by normal AUVs (i.e., nonmanipulative), a possible work scenario might also include the presence of these lasts, for accomplishing different service activities supporting the intervention ones, for instance, relays with the surface, then informative activities (for instance, the delivery of the area model built during a previous survey phase or the delivery of the intervention mission, both downloaded when in surface and then transferred to the intervention agents upon docking), or even when hovering on the work area (for instance, close to a well-recognized feature) behaving as a local reference system for the self-localization of the operative agents via twin USBL devices.

ATM Modernization

Abstract

This entry provides a broad overview of how air traffic for commercial air travel is scheduled and managed throughout the world. The major causes of delays and congestion are described, which include tight scheduling, safety restrictions, infrastructure limitations, and major disturbances. The technical and financial challenges to air traffic management are outlined, along with some of the promising developments for future modernization.

Keywords

Air traffic management; Air traffic control; Airport capacity; Airspace management; Flight safety

Introduction: How Does Air Traffic Management Work?

This entry focuses on air traffic management for commercial air travel, the passenger- and cargo-carrying operations with which most of us are familiar. This is the air travel with a pressing need for modernization to address current and future congestion. Passenger and cargo traffic is projected to double over the next 20 years, with growth rates of 3–4 % annually in developed markets such as the USA and Europe and growth rates of 6 % and more in developing markets such as Asia Pacific and the Middle East.

In most of the world, air travel is a distributed, market-driven system. Airlines schedule flights based on when people want to fly and when it is optimal to transport cargo. Most passenger flights are scheduled during the day; most package carrier flights are overnight. Some airports limit how many flights can be scheduled by having a slot system, others do not. This decentralized schedule of flights to and from airports around the world is controlled by a network of air navigation service providers (ANSPs) staffed with air traffic controllers, who ensure that aircraft are separated safely.

The International Civil Aviation Organization (ICAO) has divided the world's airspace into flight information regions. Each region has a country that controls the airspace, and the ANSP for each country can be a government department, state-owned company, or private organization. For example, in the United States, the ANSP is the Federal Aviation Administration (FAA), which is a government department. The Canadian ANSP is NAV CANADA, which is a private company.

Each country is different in terms of the services provided by the ANSP, how the ANSP operates, and the tools available to the controllers. In the USA and Europe, the airspace is divided into sectors and areas around airports. An air traffic control center is responsible for traffic flow within its sector and rules and procedures are in place to cover transfer of control between sectors. The areas around busy airports are usually handled by a terminal radar approach control. The air traffic control tower personnel handle departing aircraft, landing aircraft, and the movement of aircraft on the airport surface.

Air traffic controllers in developed air travel markets like the USA and Europe have tools that help them with the business of controlling and separating aircraft. Tower controllers operating at airports can see aircraft directly through windows or on computer screens through surveillance technology such as radar and Automatic Dependent Surveillance-Broadcast (ADS-B). Tower controllers may have additional tools to help detect and prevent potential collisions on the airport surface. En route controllers can see aircraft on computer screens and may have additional tools to help detect potential losses of separation between aircraft. Controllers can communicate with aircraft via radio and some have datalink communication available such as Controller-Pilot Datalink Communications (CPDLC).

Flight crews have tools to help with navigating and flying the airplane. Autopilots and autothrottles off-load the pilot from having to continuously control the aircraft; instead the pilot can specify the speed, altitude, and heading and the autopilot and autothrottle will maintain those commands.

Flight management systems (FMS) assist in flight planning in addition to providing lateral and vertical control of the airplane. Many aircraft have special safety systems such as the Traffic Alert and Collision Avoidance System, which alerts the flight crew to potential collisions with other airborne aircraft, and the Terrain Avoidance Warning Systems (TAWS), which alert the flight crew to potential flight into terrain.

Causes of Congestion and Delays

Congestion and delays are caused by multiple reasons. These include tight scheduling, safety limitations on how quickly aircraft can take off and land and how closely they can fly, infrastructure limitations such as the number of runways at an airport and the airway structure, and disturbances such as weather and unscheduled maintenance.

Tight Scheduling

Tight scheduling is a major contributor to congestion and delays. The hub and spoke system that many major airlines operate with to minimize connection times means that aircraft arrive and depart in multiple banks during the day. During the arrival and departure banks, airports are very busy. As mentioned previously, passengers have preferred times to travel, which also increase demand at certain times. At airports that do not limit flight schedules by using slot scheduling, the number of flights scheduled can actually exceed the departure and arrival capacity of the airport even in best-case conditions. One of the reasons that airlines are asked to report on-time statistics is to make the published airline schedules more reflective of the average time from departure to arrival, not the best-case time.

Aircraft themselves are also tightly scheduled. Aircraft are an expensive capital asset. Since customers are very sensitive to ticket prices, airlines need to have their aircraft flying as many hours as possible per day. Airlines also limit the number of spare aircraft and flight crews available to fill in when operations are disrupted to control costs.

Safety Restrictions

Safety restrictions contribute to congestion. There is a limit to how quickly aircraft can take off from and land on a runway. Sometimes runways are used for both departing and arriving aircraft; at other times a runway may be used for departures only or arrivals only. Either way, the rule that controllers follow for safety is that only one aircraft can occupy the runway at one time. Thus, a landing aircraft must turn off of the runway before another aircraft can take off or land. This limitation and other limitations like the ability of controllers to manage the arrival and departure aircraft propagate backwards from the airport. Aircraft need to be spaced in an orderly flow and separated no closer than what can be supported by airport arrival rates. The backward propagation can go all the way to the departure airports and cause aircraft to be held on the ground as a means to regulate the traffic flow into a congested airport or through a congested air traffic sector.

There is a limit on how close aircraft can fly. Aircraft produce a wake that can be dangerous for other aircraft that are following too closely behind. Pilots are aware of this limitation and space safely when doing visual separation. Rules that controllers apply for separation take into account wake turbulence limitations, surveillance limitations, and limitations on how well aircraft can navigate and conform to the required speed, altitude, and heading.

The human is a safety limitation. Controllers and pilots are human. Being human, they have excellent reasoning capability. However, they are limited as to the number of tasks they can perform and are subject to fatigue. The rules and procedures in place to manage and fly aircraft take into account human limitations.

Infrastructure Limitations

Infrastructure limitations contribute to congestion and delays. Airport capacity is one infrastructure limitation. The number of runways combined with the available aircraft gates and capacity to process passengers through the terminal limit the airport capacity.

The airspace itself is a limitation. The airspace where controllers provide separation services is divided into an orderly structure of airways. The airways are like one-way, one-lane roads in the sky. They are stacked at different altitudes, which are usually separated by either 1,000 ft. or 2,000 ft. The width of the airways depends on how well aircraft can navigate. In the US domestic airspace where there are regular navigation aids and direct surveillance of aircraft, the airways have a plus or minus 4 NM width. Over the ocean, airways may need to be separated laterally by as much as 120 NM since there are fewer navigation aids and aircraft are not under direct control but separated procedurally. The limited number of airways that the airspace can support limits available capacity.

The airways themselves have capacity limitations just as traditional roads do. There are special challenges for airways since aircraft need a minimum separation distance, aircraft cannot slow down to a stop, and airways do not allow passing. So, although it may look like there is a lot of space in which aircraft can fly, there are actually a limited number of routes between a city pair or over oceanic airspace.

The radio that is used for pilots and controllers to communicate is another infrastructure limitation. At busy airports, there is significant radio congestion and pilots may need to wait to get an instruction or response from a controller.

Disturbances

Weather is a significant disturbance in air traffic management. Weather acts negatively in many ways. Wet or icy pavement affects the braking ability of aircraft so they cannot vacate a runway as quickly as in dry conditions. Low cloud ceilings mean that all approaches must be instrument approaches rather than visual approaches, which also reduces runway arrival rates. Snow must be cleared from runways, closing them for some period of time. High winds can mean that certain approaches cannot be used because they are not safe. In extreme weather, an airport may need to close. Weather can block certain airways from use, requiring rerouting of aircraft. Rerouting increases demand on nearby airways, which may

or may not have the required additional capacity, so the rerouting cascades on both sides of the weather.

Why Is Air Traffic Management Modernization So Hard?

Air traffic management modernization is difficult for financial and technical reasons. The air traffic management system operates around the clock. It cannot be taken down for a significant period of time without a major effect on commerce and the economy.

Financing is a significant challenge for air traffic management modernization. Governments worldwide are facing budgetary challenges and improvements to air travel are one of many competing financial interests. Local airport authorities have similar challenges in raising money for airport improvements. Airlines have competitive limitations on how much ticket prices can rise and therefore need to see a payback on investment in aircraft upgrades that can be as short as 2 years.

Another financial challenge is that the entity that needs to pay for the majority of an improvement may not be the entity that gets the majority of the benefit, at least near term. One example of this is the installation of ADS-B transmitters on aircraft. Buying and installing an ADS-B transmitter costs the aircraft owner money. It benefits the ANSPs, who can receive the transmissions and have them augment or replace expensive radar surveillance, but only if a large number of aircraft are equipped. Eventually the ANSP benefit will be seen by the aircraft operator through lower operating costs but it takes time. This is one reason that ADS-B transmitter equipage was mandated in the USA, Europe, and other parts of the world rather than letting market forces drive equipage.

All entities, whether governmental or private, need some sort of business case to justify investment, where it can be shown that the benefit of the improvement outweighs the cost. The same system complexity that makes congestion and delays in one region propagate throughout the system

makes it a challenge to accurately estimate benefits. It is complicated to understand if an improvement in one part of the system will really help or just shift where the congestion points are. Decisions need to be made on what improvements are the best to invest in. For government entities, societal benefits can be as important as financial payback, and someone needs to decide whose interests are more important. For example, the people living around an airport might want longer arrival paths at night to minimize noise while air travelers and the airline want the airline to fly the most direct route into an airport. A combination of subject matter expertise and simulation can provide a starting point to estimate benefit, but often only operational deployment will provide realistic estimates.

It is a long process to develop new technologies and operational procedures even when the benefit is clear and financing is available. The typical development steps include describing the operational concept; developing new controllers procedures, pilot procedures, or phraseology if needed; performing a safety and performance analysis to determine high level requirements; performing simulations that at some point may include controllers or pilots; designing and building equipment that can include software, hardware, or both; and field testing or flight testing the new equipment. Typically, new ground tools are field tested in a shadow mode, where controllers can use the tool in a mock situation driven by real data before the tool is made fully operational. Flight testing is performed on aircraft that are flying with experimental certificates so that equipment can be tested and demonstrated prior to formal certification.

Avionics need to be certified before operational use to meet the rules established to ensure that a high safety standard is applied to air travel. To support certification, standards are developed. Frequently the standards are developed through international cooperation and through consensus decision-making that includes many different organizations such as ANSPs, airlines, aircraft manufacturers, avionics suppliers, pilot associations, controller associations, and more. This is a slow process but an important one, since it

reduces development risk for avionics suppliers and helps ensure that equipment can be used worldwide.

Once new avionics or ground tools are available, it takes time for them to be deployed. For example, aircraft fleets are upgraded as aircraft come in for major maintenance rather than pulling them out of scheduled service. Flight crews need to be trained on new equipment before it can be used, and training takes time. Ground tools are typically deployed site by site, and the controllers also require training on new equipment and new procedures.

Promise for the Future

Despite the challenges and complexity of air traffic management, there is a path forward for significant improvement in both developed and developing air travel markets. Developing air travel markets in countries like China and India can improve air traffic management using procedures, tools, and technology that is already used in developed markets such as the USA and Europe. Emerging markets like China are willing to make significant investments in improving air traffic management by building new airports, expanding existing airports, changing controller procedures, and investing in controller tools. In developed markets, new procedures, tools, and technologies will need to be implemented. In some regions, mandates and financial incentives may play a part in enabling infrastructure and equipment changes that are not driven by the marketplace.

The USA and Europe are both supporting significant research, development, and implementation programs to support air traffic management modernization. In the USA, the FAA has a program known as NextGen, the Next Generation Air Transportation System. In Europe, the European Commission oversees a program known as SESAR, the Single European Sky Air Traffic Management Research, which is a joint effort between the European Union, EUROCONTROL, and industry partners. Both programs have substantial support and

financing. Each program has organized its efforts differently but there are many similarities in the operational objectives and improvements being developed.

Airport capacity problems are being addressed in multiple ways. Controllers are being provided with advanced surface movement guidance and control systems that combine radar surveillance, ADS-B surveillance, and sensors installed at the airport with valued-added tools to assist with traffic control and alert controllers to potential collisions. Datalink communications between controllers and pilots will reduce radio-frequency congestion, reduce communication errors, and enable more complex communication. The USA and Europe have plans to develop a modernized datalink communication infrastructure between controllers and pilots that would include information like departure clearances and the taxiway route clearance. Aircraft on arrival to an airport will be controlled more precisely by equipping aircraft with capabilities such as the ability to fly to a required time of arrival and the ability to space with respect to another aircraft.

Domestic airspace congestion is being addressed in Europe by moving towards a single European sky where the ANSPs for the individual nations coordinate activities and airspace is structured not as 27 national regions but operated as larger blocks. Similar efforts are undergoing in the USA to improve the cooperation and coordination between the individual airspace sectors. In some countries, large blocks of airspace are reserved for special use by the military. In those countries, efforts are in place to have dynamic special use airspace that is reserved on an as-needed basis but otherwise available for civil use.

Oceanic airspace congestion is being addressed by leveraging the improved navigation performance of aircraft. Some route structures are available only to aircraft that can flight to a required navigation performance. These route structures have less required lateral separation, and thus more routes can be flown in the same airspace. Pilot tools that leverage ADS-B are allowing aircraft to make flight level changes with reduced separation and in the future

are expected to allow pilots to do additional maneuvering that is restricted today, such as passing slower aircraft.

Weather cannot be controlled but efforts are underway to do better prediction and provide more accurate and timely information to pilots, controllers, and aircraft dispatchers at airlines. On-board radars that pilots use to divert around weather are adding more sophisticated processing algorithms to better differentiate hazardous weather. Future flight management systems will have the capability to include additional weather information. Datalinks between the air and the ground or between aircraft may be updated to include information from the on-board radar systems, allowing aircraft to act as local weather sensors. Improved weather information for pilots, controllers, and dispatchers improves flight planning and minimizes the necessary size of deviations around hazardous weather while retaining safety.

Weather is also addressed by providing aircraft and airports with equipment to improve airport access in reduced visibility. Ground-based augmentation systems installed at airports provide aircraft with the capability to do precision-based navigation for approaches to airports with low weather ceilings. Other technologies like enhanced vision and synthetic vision, which can be part of a combined vision system, provide the capability to land in poor visibility.

Summary

Air traffic management is a complex and interesting problem. The expected increase in air travel worldwide is driving a need for improvements to the existing system so that more passengers can be handled while at the same time reducing congestion and delays. Significant research and development efforts are underway worldwide to develop safe and effective solutions that include controller tools, pilot tools, aircraft avionics, infrastructure improvements, and new procedures. Despite the technical and financial challenges, many promising technologies and new procedures will be implemented in the near, mid-, and far term to support air traffic management modernization worldwide.

Aircraft Flight Control

Dale Enns
Honeywell International Inc., Minneapolis, MN, USA

Abstract

Aircraft flight control is concerned with using the control surfaces to change aerodynamic moments, to change attitude angles of the aircraft relative to the air flow, and ultimately change the aerodynamic forces to allow the aircraft to achieve the desired maneuver or steady condition. Control laws create the commanded control surface positions based on pilot and sensor inputs. Traditional control laws employ proportional and integral compensation with scheduled gains, limiting elements, and cross feeds between coupled feedback loops. Dynamic inversion is an approach to develop control laws that systematically addresses the equivalent of gain schedules and the multivariable cross feeds, can incorporate constrained optimization for the limiting elements, and maintains the use of proportional and integral compensation to achieve the benefits of feedback.

Introduction

Flying is made possible by flight control and this applies to birds and the Wright Flyer, as well as modern flight vehicles. In addition to balancing lift and weight forces, successful flight also requires a balance of moments or torques about the mass center. Control is a means to adjust these moments to stay in equilibrium and to perform maneuvers. While birds use their feathers and the Wright Flyer warped its wings, modern flight vehicles utilize hinged control surfaces to adjust the moments. The control action can be open or closed loop, where closed loop refers to a feedback loop consisting of sensors, computer, and actuation. A direct connection between the cockpit pilot controls and the control surfaces without a feedback loop is open loop control. The computer in the feedback loop implements a control law (computer program). The development of the control law is discussed in this entry.

Although the following discussion is applicable to a wide range of flight vehicles including gliders, unmanned aerial vehicles, lifting bodies, missiles, rockets, helicopters, and satellites, the focus of this entry will be on fixed wing commercial and military aircraft with human pilots.

Flight

Aircraft are maneuvered by changing the forces acting on the mass center, e.g., a steady level turn requires a steady force towards the direction of turn. The force is the aerodynamic lift force (L) and it is banked or rotated into the direction of the turn. The direction can be adjusted with the bank angle (μ) and for a given airspeed (V) and air density (ρ), the magnitude of the force can be adjusted with the angle-of-attack (α). This is called bank-to-turn. Aircraft, e.g., missiles, can also skid-to-turn where the aerodynamic side force (Y) is adjusted with the sideslip angle (β) but this entry will focus on bank-to-turn.

Equations of motion (Enns et al. 1996; Stevens and Lewis 1992) can be used to relate the time rates of change of μ, α, and β to roll (p), pitch (q), and yaw (r) rate. See Fig. 1. Approximate relations (for near steady level flight with no wind) are

Aircraft Flight Control, Fig. 1 Flight control variables

$$\dot{\mu} = \mathsf{p}$$

$$\dot{\alpha} = q + \frac{L - m\mathsf{g}}{mV}$$

$$\dot{\beta} = -r + \frac{Y}{mV}$$

where m is the aircraft mass, and g is the gravitational acceleration. In straight and level flight conditions $L = mg$ and $Y = 0$ so we think of these equations as kinematic equations where the rates of change of the angles μ, α, and β are the angular velocities p, q, and r.

Three moments called roll, pitch, and yaw for angular motion to move the right wing up or down, nose up or down, and nose right or left, respectively create the angular accelerations to change p, q, and r, respectively. The equations are Newton's 2nd law for rotational motion. The moments (about the mass center) are dominated by aerodynamic contributions and depend on ρ, V, α, β, p, q, r, and the control surfaces. The control surfaces are aileron (δ_a), elevator (δ_e), and rudder (δ_r) and are arranged to contribute primarily roll, pitch, and yaw moments respectively.

The control surfaces (δ_a, δ_e, δ_r) contribute to angular accelerations which are integrated to obtain the angular rates (p, q, r). The integral of angular rates contributes to the attitude angles (μ, α, β). The direction and magnitude of aerodynamic forces can be adjusted with the attitude angles. The forces create the maneuvers or steady conditions for operation of the aircraft.

Pure Roll Axis Example
Consider just the roll motion. The differential equation (Newton's 2nd law for the roll degree-of-freedom) for this dynamical system is

$$\dot{\mathsf{p}} = L_{\mathsf{p}}\mathsf{p} + L_{\delta_a}\delta_a$$

where L_p is the stability derivative and $L_{\delta a}$ is the control derivative both of which can be regarded as constants for a given airspeed and air density.

Pitch Axis or Short Period Example
Consider just the pitch and heave motion. The differential equations (Newton's 2nd law for the

pitch and heave degrees-of-freedom) for this dynamical system are

$$\dot{q} = M_\alpha \alpha + M_q q + M_{\delta_e}\delta_e$$

$$\dot{\alpha} = Z_\alpha \alpha + q + Z_{\delta_e}\delta_e$$

where M_α, M_q, Z_α are stability derivatives, and $M_{\delta e}$ is the control derivative, all of which can be regarded as constants for a given airspeed and air density.

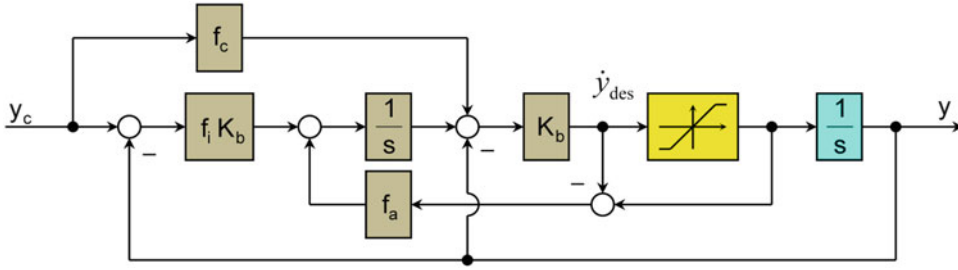
Although $Z_\alpha < 0$ and $M_q < 0$ are stabilizing, $M_\alpha > 0$ makes the short period motion inherently unstable. In fact, the short period motion of the Wright Flyer was unstable. Some modern aircraft are also unstable.

Lateral-Directional Axes Example
Consider just the roll, yaw, and side motion with four state variables (μ, p, r, β) and two inputs (δ_a, δ_r). We will use the standard state space equations with matrices A, B, C for this example.

The short period equations apply for yaw and side motion (or dutch roll motion) with appropriate replacements, e.g., q with r, α with $-\beta$, M with N. We add the term $V^{-1}g\mu$ to the $\dot{\beta}$ equation. We include the kinematic equation $\dot{\mu} = p$ and add the term $L_\beta\beta$ to the $\dot{p}$ equation. The dutch roll, like the short period, can be unstable if $N_\beta < 0$, e.g., airplanes without a vertical tail.

There is coupling between the motions associated with stability derivatives L_r, L_β, N_p and control derivatives $L_{\delta r}$ and $N_{\delta a}$. This is a fourth order multivariable coupled system where δ_a, δ_r are the inputs and we can consider (p, r) or (μ, β) as the outputs.

Control

The control objectives are to provide stability, disturbance rejection, desensitization, and satisfactory steady state and transient response to commands. Specifications and guidelines for these objectives are assessed quantitatively with frequency, time, and covariance analyses and simulations.


Aircraft Flight Control, Fig. 2 Closed loop feedback system and desired dynamics

Integrator with P + I Control

The system to be controlled is the integrator for y in Fig. 2 and the output of the integrator (y) is the controlled variable. The proportional gain ($K_b > 0$) is a frequency and sets the bandwidth or crossover frequency of the feedback loop. The value of K_b will be between 1 and 10 rad/s in most aircraft applications. Integral action can be included with the gain, $f_i > 0$ with a value between 0 and 1.5 in most applications. The value of the command gain, $f_c > 0$, is set to achieve a desired closed loop response from the command y_c to the output y. Values of $f_i = 0.25$ and $f_c = 0.5$ are typical. In realistic applications, there is a limit that applies at the input to the integrator. In these cases, we are obligated to include an anti-integral windup gain, $f_a > 0$ (typical value of 2) to prevent continued integration beyond the limit. The input to the limiter ($\dot{y}_{des}$) is called the desired rate of change of the controlled variable (Enns et al. 1996).

The closed loop transfer function is

$$\frac{y}{y_c} = \frac{K_b(f_c s + f_i K_b)}{s^2 + K_b s + f_i K_b^2}$$

and the pilot produces the commands, (y_c) with cockpit inceptors, e.g., sticks, pedals.

The control system robustness can be adjusted with the choices made for y, K_b, f_i, and f_c.

These desired dynamics are utilized in all of the examples to follow. In the following, we use dynamic inversion (Enns et al. 1996; Wacker et al. 2001) to algebraically manipulate the equations of motion into the equivalent of the integrator for y in Fig. 2.

Pure Roll Motion Example

With algebraic manipulations called dynamic inversion we can use the pure integrator results in the previous section for the pure roll motion example. For the controlled variable $y = p$, given a measurement of the state $x = p$ and values for L_p and $L_{\delta a}$, we simply solve for the input ($u = \delta_a$) that gives the desired rate of change of the output $\dot{y}_{des} = \dot{p}_{des}$. The solution is

$$\delta_a = L_{\delta_a}^{-1}(\dot{p}_{des} - L_p p)$$

Since $L_{\delta a}$ and L_p vary with air density and airspeed, we are motivated to schedule these portions of the control law accordingly.

Short Period Example

Similar algebraic manipulations use the general state space notation

$$\dot{x} = Ax + Bu$$
$$y = Cx$$

We want to solve for u to achieve a desired rate of change of y, so we start with

$$\dot{y} = CAx + CBu$$

If we can invert CB, i.e., it is not zero, for the short period case, we solve for u with

$$u = (CB)^{-1}(\dot{y}_{des} - CAx)$$

Implementation requires a measurement of the state, x and models for the matrices CA and CB.

The closed loop poles include the open loop zeros of the transfer function $\frac{y(s)}{u(s)}$ (zero dynamics) in addition to the roots of the desired dynamics characteristic equation. Closed loop stability requires stable zero dynamics. The zero dynamics have an impact on control system robustness and can influence the precise choice of y.

When $y = q$, the control law includes the following dynamic inversion equation

$$\delta_e = M_{\delta_e}^{-1}(\dot{q}_{\text{des}} - M_q q - M_\alpha \alpha)$$

and the open loop zero is $Z_\alpha - Z_{\delta_e} M_{\delta_e}^{-1} M_\alpha$, which in almost every case of interest is a negative number.

Note that there are no restrictions on the open loop poles. This control law is effective and practical in stabilization of an aircraft with an open loop unstable short period mode.

Since $M_{\delta e}$, M_q and M_α vary with air density and airspeed we are motivated to schedule these portions of the control law accordingly.

When $y = \alpha$, the zero dynamics are not suitable as closed loop poles. In this case, the pitch rate controller described above is the inner loop and we apply dynamic inversion a second time as an outer loop (Enns and Keviczky 2006) where we approximate the angle-of-attack dynamics with the simplification that pitch rate has reached steady state, i.e., $\dot{q} = 0$ and regard pitch rate as the input ($u = q$) and angle-of-attack as the controlled variable ($y = \alpha$). The approximate equation of motion is

$$\dot{\alpha} = Z_\alpha \alpha + q - Z_{\delta_e} M_{\delta_e}^{-1} \left(M_\alpha \alpha + M_q q \right)$$
$$= \left(Z_\alpha - Z_{\delta_e} M_{\delta_e}^{-1} M_\alpha \right) \alpha$$
$$+ \left(1 - Z_{\delta_e} M_{\delta_e}^{-1} M_q \right) q$$

This equation is inverted to give

$$q_c = \left(1 - Z_{\delta_e} M_{\delta_e}^{-1} M_q \right)^{-1}$$
$$\left[\dot{\alpha}_{\text{des}} - \left(Z_\alpha - Z_{\delta_e} M_{\delta_e}^{-1} M_\alpha \right) \alpha \right]$$

q_c obtained from this equation is passed to the inner loop as a command, i.e., y_c of the inner loop.

Lateral-Directional Example

If we choose the two angular rates as the controlled variables (p, r), then the zero dynamics are favorable. We use the same proportional plus integral desired dynamics in Fig. 2 but there are two signals represented by each wire (one associated with p and the other r).

The same state space equations are used for the dynamic inversion step but now CA and CB are 2×4 and 2×2 matrices, respectively instead of scalars. The superscript in $u = (CB)^{-1}(\dot{y}_{\text{des}} - CAx)$ now means matrix inverse instead of reciprocal. The zero dynamics are assessed with the transmission zeros of the matrix transfer function $(p, r)/(\delta_a, \delta_r)$.

In the practical case where the aileron and rudder are limited, it is possible to place a higher priority on solving one equation vs. another if the equations are coupled, by proper allocation of the commands to the control surfaces which is called control allocation (Enns 1998). In these cases, we use a constrained optimization approach

$$\min_{u_{\text{min}} \leq u \leq u_{\text{max}}} ||CBu - (\dot{y}_{\text{des}} - CAx)||$$

instead of the matrix inverse followed by a limiter. In cases where there are redundant controls, i.e., the matrix CB has more columns than rows, we introduce a preferred solution, u_p and solve a different constrained optimization problem

$$\min_{CBu+CAx=\dot{y}_{\text{des}}} ||u - u_p||$$

to find the solution that solves the equations that is closest to the preferred solution. We utilize weighted norms to accomplish the desired priority.

An outer loop to control the attitude angles (μ, β) can be obtained with an approach analogous to the one used in the previous section.

Nonlinear Example

Dynamic inversion can be used directly with the nonlinear equations of motion (Enns et al. 1996; Wacker et al. 2001). General equations of motion, e.g., 6 degree-of-freedom rigid body can be expressed with $\dot{x} = f(x, u)$ and the controlled

variable is given by $y = h(x)$. With the chain rule of calculus we obtain

$$\dot{y} = \frac{\partial h}{\partial x}(x)\, f(x, u)$$

and for a given $\dot{y} = \dot{y}_{\text{des}}$ and (measured) x we can solve this equation for u either directly or approximately. In practice, the first order Taylor Series approximation is effective

$$\dot{y} \cong a(x, u_0) + b(x, u_0)(u - u_0)$$

where u_0 is typically the past value of u, in a discrete implementation. As in the previous example, Fig. 2 can be used to obtain $\dot{y}_{\text{des}}$. The terms $a(x, u_0) - b(x, u_0)\, u_0$ and $b(x, u_0)$ are analogous to the terms CAx and the matrix CB, respectively. Control allocation can be utilized in the same way as discussed above. The zero dynamics are evaluated with transmission zeros at the intended operating points. Outer loops can be employed in the same manner as discussed in the previous section.

The control law with this approach utilizes the equations of motion which can include table lookup for aerodynamics, propulsion, mass properties, and reference geometry as appropriate. The raw aircraft data or an approximation to the data takes the place of gain schedules with this approach.

portions of the control law are scheduled. Aircraft do exhibit coupling between axes and so multivariable feedback loop approaches are effective. Nonlinearities in the form of limits (noninvertible) and nonlinear expressions, e.g., trigonometric, polynomial, and table look-up (invertible) are present in flight control development. The dynamic inversion approach has been shown to include the traditional feedback control principles, systematically develops the equivalent of the gain schedules, applies to multivariable systems, applies to invertible nonlinearities, and can be used to avoid issues with noninvertible nonlinearities to the extent it is physically possible.

Future developments will include adaptation, reconfiguration, estimation, and nonlinear analyses. Adaptive control concepts will continue to mature and become integrated with approaches such as dynamic inversion to deal with unstructured or nonparameterized uncertainty or variations in the aircraft dynamics. Parameterized uncertainty will be incorporated with near real time reconfiguration of the aircraft model used as part of the control law, e.g., reallocation of control surfaces after an actuation failure. State variables used as measurements in the control law will be estimated as well as directly measured in nominal and sensor failure cases. Advances in nonlinear dynamical systems analyses will create improved intuition, understanding, and guidelines for control law development.

Summary and Future Directions

Flight control is concerned with tracking commands for angular rates. The commands may come directly from the pilot or indirectly from the pilot through an outer loop, where the pilot directly commands the outer loop. Feedback control enables stabilization of aircraft that are inherently unstable and provides disturbance rejection and insensitive closed-loop response in the face of uncertain or varying vehicle dynamics. Proportional and integral control provide these benefits of feedback. The aircraft dynamics are significantly different for low altitude and high speed compared to high altitude and low speed and so

Applications of Discrete-Event Systems

Spyros Reveliotis
School of Industrial & Systems Engineering,
Georgia Institute of Technology, Atlanta,
GA, USA

Abstract

This entry provides an overview of the problems addressed by discrete-event systems (DES) theory, with an emphasis on their connection to various application contexts. The primary intentions are to reveal the caliber and the strengths of this theory and to direct the interested reader, through the listed citations, to the corresponding literature. The concluding part of the entry also identifies some remaining challenges and further opportunities for the area.

Keywords

Applications; Discrete-event systems

Introduction

Discrete-event systems (DES) theory (▶ Models for Discrete Event Systems: An Overview) (Cassandras and Lafortune 2008) emerged in the late 1970s/early 1980s from the effort of the controls community to address the control needs of applications concerning some complex production and service operations, like those taking place in manufacturing and other workflow systems, telecommunication and data-processing systems, and transportation systems. These operations were seeking the ability to support higher levels of efficiency and productivity and more demanding notions of quality of product and service. At the same time, the thriving computing technologies of the era, and in particular the emergence of the microprocessor, were cultivating, and to a significant extent supporting, visions of ever-increasing automation and autonomy for the aforementioned operations. The DES community set out to provide a systematic and rigorous understanding of the dynamics that drive the aforementioned operations and their complexity, and to develop a control paradigm that would define and enforce the target behaviors for those environments in an effective and robust manner.

In order to address the aforementioned objectives, the controls community had to extend its methodological base, borrowing concepts, models, and tools from other disciplines. Among these disciplines, the following two played a particularly central role in the development of the DES theory: (i) the Theoretical Computer Science (TCS) and (ii) the Operations Research (OR). As a new research area, DES thrived on the analytical strength and the synergies that resulted from the rigorous integration of the modeling frameworks that were borrowed from TCS and OR. Furthermore, the DES community substantially extended those borrowed frameworks, bringing in them many of its control-theoretic perspectives and concepts.

In general, DES-based approaches are characterized by (i) their emphasis on a rigorous and formal representation of the investigated systems and the underlying dynamics; (ii) a double focus on time-related aspects and metrics that define traditional/standard notions of performance for the considered systems, but also on a more behaviorally oriented analysis that is necessary for ensuring fundamental notions of "correctness," "stability," and "safety" of the system operation,

especially in the context of the aspired levels of autonomy; (iii) the interplay between the two lines of analysis mentioned in item (ii) above and the further connection of this analysis to structural attributes of the underlying system; and (iv) an effort to complement the analytical characterizations and developments with design procedures and tools that will provide solutions provably consistent with the posed specifications and effectively implementable within the time and other resource constraints imposed by the "real-time" nature of the target applications.

The rest of this entry overviews the current achievements of DES theory with respect to (w.r.t.) the different classes of problems that have been addressed by it and highlights the potential that is defined by these achievements for a range of motivating applications. On the other hand, the constricted nature of this entry does not allow an expansive treatment of the aforementioned themes. Hence, the provided coverage is further supported and supplemented by an extensive list of references that will connect the interested reader to the relevant literature.

A Tour of DES Problems and Applications

DES-Based Behavioral Modeling, Analysis, and Control

The basic characterization of behavior in the DES-theoretic framework is through the various event sequences that can be generated by the underlying system. Collectively, these sequences are known as the (formal) language generated by the plant system, and the primary intention is to restrict the plant behavior within a subset of the generated event strings. The investigation of this problem is further facilitated by the introduction of certain mechanisms that act as formal representations of the studied systems, in the sense that they generate the same strings of events (i.e., the same formal language). Since these models are concerned with the representation of the event sequences that are generated by DES, and not by the exact timing of these events, they are

frequently characterized as *untimed* DES models. In the practical applications of DES theory, the most popular such models are the Finite State Automaton (FSA) (Cassandras and Lafortune 2008; Hopcroft and Ullman 1979; ▶ Supervisory Control of Discrete-Event Systems; ▶ Diagnosis of Discrete Event Systems), and the Petri net (PN) (Cassandras and Lafortune 2008; Murata 1989; ▶ Modeling, Analysis, and Control with Petri Nets).

In the context of DES applications, these modeling frameworks have been used to provide succinct characterizations of the underlying event-driven dynamics and to design controllers, in the form of supervisors, that will restrict these dynamics so that they abide to safety, consistency, fairness, and other similar considerations (▶ Supervisory Control of Discrete-Event Systems). As a more concrete example, in the context of contemporary manufacturing, DES-based behavioral control – frequently referred to as supervisory control (SC) – has been promoted as a systematic methodology for the synthesis and verification of the control logic that is necessary for the support of the, so-called, SCADA (Supervisory Control and Data Acquisition) function. This control function is typically implemented through the Programmable Logic Controllers (PLCs) that have been employed in contemporary manufacturing shop-floors, and DES SC theory can support it (i) by providing more rigor and specificity to the models that are employed for the underlying plant behavior and the imposed specifications and (ii) by offering the ability to synthesize control policies that are provably correct by construction. Some example works that have pursued the application of DES SC along these lines can be found in Balemi et al. (1993), Brandin (1996), Park et al. (1999), Chandra et al. (2003), Endsley et al. (2006), and Andersson et al. (2010).

On the other hand, the aforementioned activity has also defined a further need for pertinent interfaces that will translate (a) the plant structure and the target behavior to the necessary DES-theoretic models and (b) the obtained policies to PLC executables. This need has led to a line of research, in terms of representational models and

computational tools, that is complementary to the core DES developments described in the previous paragraphs. Indicatively we mention the development of GRAFCET (David and Alla 1992) and of the sequential function charts (SFCs) (Lewis 1998) from the earlier times, while some more recent endeavor along these lines is reported in Wightkin et al. (2011) and Alenljung et al. (2012) and the references cited therein.

Besides its employment in the manufacturing domain, DES SC theory has also been considered for the coordination of the communicating processes that take place in various embedded systems (Feng et al. 2007); the systematic validation of the embedded software that is employed in various control applications, ranging from power systems and nuclear plants to aircraft and automotive electronics (Li and Kumar 2012); the synthesis of the control logic in the electronic switches that are utilized in telecom and data networks; and the modeling, analysis, and control of the operations that take place in health-care systems (Sampath et al. 2008). Wassyng et al. (2011) gives a very interesting account of the gains, but also the extensive challenges, experienced by a team of researchers who have tried to apply formal methods, similar to those that have been promoted by the behavioral DES theory, to the development and certification of the software that manages some safety-critical operations for Canadian nuclear plants.

Apart from control, untimed DES models have also been employed for the diagnosis of critical events, like certain failures, that cannot be observed explicitly, but their occurrence can be inferred from some resultant behavioral patterns (Sampath et al. 1996; ▶ Diagnosis of Discrete Event Systems). More recently, the relevant methodology has been extended with prognostic capability (Kumar and Takai 2010), while an interesting variation of it addresses the "dual" problem that concerns the design of systems where certain events or behavioral patterns must remain undetectable by an external observer who has only partial observation of the system behavior; this last requirement has been formally characterized by the notion of "opacity" in the relevant literature, and it finds application

in the design and operation of secure systems (Dubreil et al. 2010; Saboori and Hadjicostis 2012, 2014).

Dealing with the Underlying Computational Complexity

As revealed from the discussion of the previous paragraphs, many of the applications of DES SC theory concern the integration and coordination of behavior that is generated by a number of interacting components. In these cases, the formal models that are necessary for the description of the underlying plant behavior may grow their size very fast, and the algorithms that are involved in the behavioral analysis and control synthesis may become practically intractable. Nevertheless, the rigorous methodological base that underlies DES theory provides also a framework for addressing these computational challenges in an effective and structured manner.

More specifically, DES SC theory provides conditions under which the control specifications can be decomposable to the constituent plant components while maintaining the integrity and correctness of the overall plant behavior (▶ Supervisory Control of Discrete-Event Systems; Wonham 2006). The aforementioned works of Brandin (1996) and Endsley et al. (2006) provide some concrete examples for the application of modular control synthesis. On the other hand, there are fundamental problems addressed by SC theory and practice that require a holistic view of the underlying plant and its operation, and thus, they are not amenable to modular solutions. For such cases, DES SC theory can still provide effective solutions through (i) the identification of special plant structure, of practical relevance, for which the target supervisors are implementable in a computationally efficient manner and (ii) the development of structured approaches that can systematically trade-off the original specifications for computational tractability.

A particular application that has benefited from, and, at the same time, has significantly promoted this last capability of DES SC theory, is that concerning the deadlock-free operation of many systems where a set of processes that execute concurrently and in a staged manner are

competing, at each of their processing stages, for the allocation of a finite set of reusable resources. In DES theory, this problem is known as the liveness-enforcing supervision of sequential resource allocation systems (RAS) (Reveliotis 2005), and it underlies the operation of many contemporary applications: from the resource allocation taking place in contemporary manufacturing shop floors, Ezpeleta et al. (1995), Reveliotis and Ferreira (1996), and Jeng et al. (2002), to the traveling and/or work-space negotiation in robotic systems (Reveliotis and Roszkowska 2011), automated railway (Giua et al. 2006), and other guidepath-based traffic systems (Reveliotis 2000); to Internet-based workflow management systems like those envisioned for e-commerce and certain banking and insurance claim processing applications (Van der Aalst 1997); and to the allocation of the semaphores that control the accessibility of shared resources by concurrently executing threads in parallel computer programs (Liao et al. 2013). A systematic introduction to the DES-based modeling of RAS and their liveness-enforcing supervision is provided in Reveliotis (2005) and Zhou and Fanti (2004), while some more recent developments in the area are epitomized in Reveliotis (2007), Li et al. (2008) and Reveliotis and Nazeem (2013).

Closing the above discussion on the ability of DES theory to address effectively the complexity that underlies the DES SC problem, we should point out that the same merits of the theory have also enabled the effective management of the complexity that underlies problems related to the performance modeling and control of the various DES applications. We shall return to this capability in the next section that discusses the achievements of DES theory in this domain.

DES Performance Control and the Interplay Among Structure, Behavior, and Performance

DES theory is also interested in the performance modeling, analysis, and control of its target applications w.r.t. time-related aspects like throughput, resource utilization, experienced latencies, and congestion patterns. To support this type of analysis, the untimed DES behavioral models are extended to their *timed* versions. This extension takes place by endowing the original untimed models with additional attributes that characterize the experienced delays between the activation of an event and its execution (provided that it is not preempted by some other conflicting event). Timed models are further classified by the extent and the nature of the randomness that is captured by them. A basic such categorization is between deterministic models, where the aforementioned delays take fixed values for every event and stochastic models which admit more general distributions. From an application standpoint, timed DES models connect DES theory to the multitude of applications that have been addressed by Dynamic Programming, Stochastic Control, and scheduling theory (Bertsekas 1995; Meyn 2008; Pinedo 2002). Also, in their most general definition, stochastic DES models provide the theoretical foundation of discrete-event simulation (Banks et al. 2009).

Similar to the case of behavioral DES theory, a practical concern that challenges the application of timed DES models for performance modeling, analysis, and control is the very large size of these models, even for fairly small systems. DES theory has tried to circumvent these computational challenges through the development of methodology that enables the assessment of the system performance, over a set of possible configurations, from the observation of its behavior and the resultant performance at a single configuration. The required observations can be obtained through simulation, and in many cases, they can be collected from a single realization – or sample path – of the observed behavior; but then, the considered methods can also be applied on the actual system, and thus, they become a tool for real-time optimization, adaptation, and learning. Collectively, the aforementioned methods define a "sensitivity"-based approach to DES performance modeling, analysis, and control (Cassandras and Lafortune 2008; ▶ Perturbation Analysis of Discrete Event Systems). Historically, DES sensitivity analysis originated in the early 1980s in an effort to address the performance

analysis and optimization of queueing systems w.r.t. certain structural parameters like the arrival and processing rates (Ho and Cao 1991). But the current theory addresses more general stochastic DES models that bring it closer to broader endeavors to support incremental optimization, approximation, and learning in the context of stochastic optimal control (Cao 2007). Some particular applications of DES sensitivity analysis for the performance optimization of production, telecom, and computing systems can be found in Cassandras and Strickland (1988), Cassandras (1994), Panayiotou and Cassandras (1999), Homem-de Mello et al. (1999), Fu and Xie (2002), and Santoso et al. (2005).

Another interesting development in time-based DES theory is the theory of (max,+) algebra (Baccelli et al. 1992). In its practical applications, this theory addresses the timed dynamics of systems that involve the synchronization of a number of concurrently executing processes with no conflicts among them, and it provides important structural results on the factors that determine the behavior of these systems in terms of the occurrence rates of various critical events and the experienced latencies among them. Motivational applications of (max,+) algebra can be traced in the design and control of telecommunication and data networks, manufacturing, and railway systems, and more recently the theory has found considerable practical application in the computation of repetitive/cyclical schedules that seek to optimize the throughput rate of automated robotic cells and of the cluster tools that are used in semiconductor manufacturing (Kim and Lee 2012; Lee 2008; Park et al. 1999).

Both sensitivity-based methods and the theory of (max,+) algebra that were discussed in the previous paragraphs are enabled by the explicit, formal modeling of the DES structure and behavior in the pursued performance analysis and control. This integrative modeling capability that is supported by DES theory also enables a profound analysis of the impact of the imposed behavioral-control policies upon the system performance and, thus, the pursuance of a more integrative approach to the synthesis of the behavioral and

the performance-oriented control policies that are necessary for any particular DES instantiation. This is a rather novel topic in the relevant DES literature, and some recent works in this direction can be found in Cao (2005), Li and Reveliotis (2013), Markovski and Su (2013), and David-Henriet et al. (2013).

The Roles of Abstraction and Fluidification

The notions of "abstraction" and "fluidification" play a significant role in mastering the complexity that arises in many DES applications. Furthermore, both of these concepts have an important role in defining the essence and the boundaries of DES-based modeling.

In general systems theory, abstraction can be broadly defined as the effort to develop simplified models for the considered dynamics that retain, however, adequate information to resolve the posed questions in an effective manner. In DES theory, abstraction has been pursued w.r.t. the modeling of both the timed and untimed behaviors, giving rise to hierarchical structures and models. A theory for hierarchical SC is presented in Wonham (2006), while some applications of hierarchical SC in the manufacturing domain are presented in Hill et al. (2010) and Schmidt (2012). In general, hierarchical SC relies on a "spatial" decomposition that tries to localize/encapsulate the plant behavior into a number of modules that interact through the communication structure that is defined by the hierarchy. On the other hand, when it comes to timed DES behavior and models, a popular approach seeks to define a hierarchical structure for the underlying decision-making process by taking advantage of the different time scales that correspond to the occurrence of the various event types. Some particular works that formalize and systematize this idea in the application context of production systems can be found in Gershwin (1994) and Sethi and Zhang (1994) and the references cited therein.

In fact, the DES models that have been employed in many application areas can be perceived themselves as abstractions of dynamics of a more continuous, time-driven nature, where the underlying plant undergoes some fundamental

(possibly structural) transition upon the occurrence of certain events that are defined either endogenously or exogenously w.r.t. these dynamics. The combined consideration of the discrete-event dynamics that are generated in the manner described above, with the continuous, time-driven dynamics that characterize the modalities of the underlying plant, has led to the extension of the original DES theory to the, so-called, hybrid systems theory. Hybrid systems theory is itself very rich, and it is covered in another section of this encyclopedia (see also ▶ Discrete Event Systems and Hybrid Systems, Connections Between). From an application standpoint, it increases substantially the relevance of the DES modeling framework and brings this framework to some new and exciting applications. Some of the most prominent applications concern the coordination of autonomous vehicles and robotic systems, and a nice anthology of works concerning the application of hybrid systems theory in this particular application area can be found in the IEEE Robotics and Automation magazine of September 2011. These works also reveal the strong affinity that exists between hybrid systems theory and the DES modeling paradigm. Along similar lines, hybrid systems theory underlies also the endeavors for the development of the Automated Highway Systems that have been explored for the support of the future urban traffic needs (Horowitz and Varaiya 2000). Finally, hybrid systems theory and its DES component have been explored more recently as potential tools for the formal modeling and analysis of the molecular dynamics that are studied by systems biology (Curry 2012).

Fluidification, on the other hand, is the effort to represent as continuous flows, dynamics that are essentially of discrete-event type, in order to alleviate the computational challenges that typically result from discreteness and its combinatorial nature. The resulting models serve as approximations of the original dynamics, frequently they have the formal structure of hybrid systems, and they define a basis for developing "relaxations" for the originally addressed problems. Usually, their justification is of an *ad hoc* nature, and the quality of the established

approximations is empirically assessed on the basis of the delivered results (by comparing these results to some "baseline" performance). There are, however, a number of cases where the relaxed fluid model has been shown to retain important behavioral attributes of its original counterpart (Dai 1995). Furthermore, some recent works have investigated more analytically the impact of the approximation that is introduced by these models on the quality of the delivered results (Wardi and Cassandras 2013). Some more works regarding the application of fluidification in the DES-theoretic modeling frameworks, and of the potential advantages that it brings in various application contexts, can be found in Srikant (2004), Meyn (2008), David and Alla (2005), and Cassandras and Yao (2013).

Summary and Future Directions

The discussion of the previous section has revealed the extensive application range and potential of DES theory and its ability to provide structured and rigorous solutions to complex and sometimes ill-defined problems. On the other hand, the same discussion has revealed the challenges that underlie many of the DES applications. The complexity that arises from the intricate and integrating nature of most DES models is perhaps the most prominent of these challenges. This complexity manifests itself in the involved computations, but also in the need for further infrastructure, in terms of modeling interfaces and computational tools, that will render DES theory more accessible to the practitioner.

The DES community is aware of this need, and the last few years have seen the development of a number of computational platforms that seek to implement and leverage the existing theory by connecting it to various application settings; indicatively, we mention DESUMA (Ricker et al. 2006), SUPREMICA (Akesson et al. 2006), and TCT (Feng and Wonham 2006) that support DES behavioral modeling, analysis, and control along the lines of DES SC theory, while the website entitled "The Petri Nets World" has an extensive database of tools that support modeling and

analysis through untimed and timed variations of the Petri net model. Model checking tools, like SMV and NuSpin, that are used for verification purposes are also important enablers for the practical application of DES theory, and, of course, there are a number of programming languages and platforms, like Arena, AutoMod, and Simio, that support discrete-event simulation. However, with the exception of the discrete-event-simulation software, which is a pretty mature industry, the rest of the aforementioned endeavors currently evolve primarily within the academic and the broader research community. Hence, a remaining challenge for the DES community is the strengthening and expansion of the aforementioned computational platforms to robust and user-friendly computational tools. The availability of such industrial-strength computational tools, combined with the development of a body of control engineers well-trained in DES theory, will be catalytic for bringing all the developments that were described in the earlier parts of this document even closer to the industrial practice.

Auctions

Bruce Hajek
University of Illinois, Urbana, IL, USA

Abstract

Auctions are procedures for selling one or more items to one or more bidders. Auctions induce games among the bidders, so notions of equilibrium from game theory can be applied to auctions. Auction theory aims to characterize and compare the equilibrium outcomes for different types of auctions. Combinatorial auctions arise when multiple-related items are sold simultaneously.

Keywords

Auction; Combinatorial auction; Game theory

Introduction

Three commonly used types of auctions for the sale of a single item are the following:

- *First price auction:* Each bidder submits a bid one of the bidders submitting the maximum bid wins, and the payment for the item is the maximum bid. (In this context "wins" means receives the item, no matter what the payment.)
- *Second price auction* or *Vickrey auction*: Each bidder submits a bid, one of the bidders submitting the maximum bid wins, and the payment for the item is the second highest bid.
- *English auction:* The price for the item increases continuously or in some small increments, and bidders drop out at some points in time. Once all but one of the bidders has dropped out, the remaining bidder wins and the payment is the price at which the last of the other bidders dropped out.

A key goal of the theory of auctions is to predict how the bidders will bid, and predict the resulting outcomes of the auction: which bidder is the winner and what is the payment. For example, a seller may be interested in the expected payment (seller revenue). A seller may have the option to choose one auction format over another and be interested in revenue comparisons. Another item of interest is efficiency or social welfare. For sale of a single item, the outcome is efficient if the item is sold to the bidder with the highest value for the item. The book of V. Krishna (2002) provides an excellent introduction to the theory of auctions.

Auctions Versus Seller Mechanisms

An important class of mechanisms within the theory of mechanism design are seller mechanisms, which implement the sale of one or more items to one or more bidders. Some authors would consider all such mechanisms to be auctions, but the definition of auctions is often more narrowly interpreted, with auctions being the subclass of seller mechanisms which do not depend on the fine details of the set of bidders. The rules of the three types of auction mentioned above do not depend on fine details of the bidders, such as the number of bidders or statistical information about how valuable the item is to particular bidders. In contrast, designing a procedure to sell an item to a known set of bidders under specific statistical assumptions about the bidders' preferences in order to maximize the expected revenue (as in Myerson (1981)) would be considered a problem of mechanism design, which is outside the more narrowly defined scope of auctions. The narrower definition of auctions was championed by R. Wilson (1987). An article on ▶ Mechanism Design appears in this encyclopedia.

Equilibrium Strategies in Auctions

An auction induces a noncooperative game among the bidders, and a commonly used predictor of the outcome of the auction is an equilibrium of the game, such as a Nash or Bayes-Nash equilibrium. For a risk neutral bidder i with value x_i for the item, if the bidder wins and the payment is M_i, the payoff of the bidder is $x_i - M_i$. If the bidder does not win, the payoff of the bidder is zero. If, instead, the bidder is risk averse with risk aversion measured by an increasing utility function u_i, the payoff of the bidder would be $u_i(x_i - M_i)$ if the bidder wins and $u_i(0)$ if the bidder does not win.

The second price auction format is characterized by simplicity of the bidding strategies. If bidder i knows the value x_i of the item to himself, then for the second price auction format, a weakly dominant strategy for the bidder is to truthfully report x_i as his bid for the item. Indeed, if y_i is the highest bid of the other bidders, the payoff of bidder i is $u_i(x_i - y_i)$ if he wins and $u_i(0)$ if he does not win. Thus, bidder i would prefer to win whenever $u_i(x_i - y_i) > u_i(0)$ and not win whenever $u_i(x_i - y_i) < u_i(0)$. That is precisely what happens if bidder i bids x_i, no matter what the bids of the other bidders are. That is, bidding x_i is a weakly dominant strategy for bidder i.

Nash equilibrium can be found for the other types of auctions under a model with incomplete information, in which the type of each bidder i is equal to the value of the object to the bidder and is modeled as a random variable X_i with a density function f_i supported by some interval $[a_i, b_i]$. A simple case is that the bidders are all risk neutral, the densities are all equal to some fixed density f, and the X_i's are mutually independent. The English auction in this context is equivalent to the second price auction: in an English auction, dropping out when the price reaches his true value is a weakly dominant strategy for a bidder, and for the weakly dominant strategy equilibrium, the outcome of the auction is the same as for the second price auction. For the first price auction in this symmetric case, there exists a symmetric Bayesian equilibrium. It corresponds to all bidders using the bidding function β (so the bid of bidder i is $\beta(X_i)$), where β is given by $\beta(x) = E[Y_1|Y_1 \leq x]$. The expected revenue to the seller in this case is $E[Y_1|Y_1 < X_1]$, which is the same as the expected revenue for the second price auction and English auction.

Equilibrium for Auctions with Interdependent Valuations

Seminal work of Milgrom and Weber (1982) addresses the performance of the above three auction formats in case the bidders do not know the value of the item, but each bidder i has a private signal X_i about the value V_i of the item to bidder i. The values and signals $(X_1, \ldots X_n, V_1, \ldots, V_n)$ can be interdependent. Under the assumption of invariance of the joint distribution of $(X_1, \ldots X_n, V_1, \ldots, V_n)$ under permutation of the bidders and a strong form of positive correlation of the random

variables $(X_1, \ldots X_n, V_1, \ldots, V_n)$ (see Milgrom and Weber 1982 or Krishna 2002 for details), a symmetric Bayes-Nash equilibrium is identified for each of the three auction formats mentioned above, and the expected revenues for the three auction formats are shown to satisfy the ordering $R^{(\text{first price})} \leq R^{(\text{second price})} \leq R^{(\text{English})}$. A significant extension of the theory of Milgrom and Weber due to DeMarzo et al. (2005) is the theory of security-bid auctions in which bidders compete to buy an asset and the final payment is determined by a contract involving the value of the asset as revealed after the auction.

Combinatorial Auctions

Combinatorial auctions implement the simultaneous sale of multiple items. A simple version is the simultaneous ascending price auction with activity constraints (Cramton 2006; Milgrom 2004). Such an auction procedure was originally proposed by Preston, McAfee, Paul Milgrom, and Robert Wilson for the US FCC wireless spectrum auction in 1994 and was used for the vast majority of spectrum auctions worldwide since then Cramton (2013). The auction proceeds in rounds. In each round a minimum price is set for each item, with the minimum prices for the initial round being reserve prices set by the seller. A given bidder may place a bid on an item in a given round such that the bid is greater than or equal to the minimum price for the item. If one or more bidders bid on an item in a round, a provisional winner of the item is selected from among the bidders with the highest bid for the item in the round, with the new provisional price being the highest bid. The minimum price for the item is increased 10 % (or some other small percentage) above the new provisional price. Once there is a round with no bids, the set of provisional winners is identified. Often constraints are placed on the bidders in the form of *activity rules.* An activity rule requires a bidder to maintain a history of bidding in order to continue bidding, so as to prevent bidders from not bidding in early rounds and bidding aggressively in later rounds. The motivation for activity rules is to promote *price*

discovery to help bidders select the packages (or bundles) of items most suitable for them to buy. A key is that complementarities may exist among the items for a given bidder. Complementarity means that a bidder may place a significantly higher value on a bundle of items than the sum of values the bidder would place on the items individually. Complementarities lead to the *exposure problem*, which occurs when a bidder wins only a subset of items of a desired bundle at a price which is significantly higher than the price paid. For example, a customer might place a high value on a particular pair of shoes, but little value on a single shoe alone.

A variation of simultaneous ascending price auctions for combinatorial auctions is auctions with package bidding (see, e.g., Ausubel and Milgrom 2002; Cramton 2013). A bidder will either win a package of items he bid for or no items, thereby eliminating the exposure problem. For example, in simultaneous clock auctions with package bidding, the price for each item increases according to a fixed schedule (the clock), and bidders report the packages of items they would prefer to purchase for the given prices. The price for a given item stops increasing when the number of bidders for that item drops to zero or one, and the clock phase of the auction is complete when the number of bidders for every item is zero or one. Following the clock phase, bidders can submit additional bids for packages of items. With the inputs from bidders acquired during the clock phase and supplemental bid phase, the auctioneer then runs a winner determination algorithm to select a set of bids for non-overlapping packages that maximizes the sum of the bids. This winner determination problem is NP hard, but is computationally feasible using integer programming or dynamic programming methods for moderate numbers of items (perhaps up to 30). In addition, the vector of payments charged to the winners is determined by a two-step process. First, the (generalized) Vickrey price for each bidder is determined, which is defined to be the minimum the bidder would have had to bid in order to be a winner. Secondly, the vector of Vickrey prices is projected onto the core of the reported prices. The second step insures that no coalition

consisting of a set of bidders and the seller can achieve a higher sum of payoffs (calculated using the bids received) for some different selection of winners than the coalition received under the outcome of the auction. While this is a promising family of auctions, the projection to the core introduces some incentive for bidders to deviate from truthful reporting, and much remains to be understood about such auctions.

Summary and Future Directions

Auction theory provides a good understanding of the outcomes of the standard auctions for the sale of a single item. Recently emerging auctions, such as for the generation and consumption of electrical power, and for selection of online advertisements, are challenging to analyze and comprise a direction for future research. Much remains to be understood in the theory of combinatorial auctions, such as the degree of incentive compatibility offered by core projecting auctions.

Autotuning

Tore Hägglund
Lund University, Lund, Sweden

Abstract

Autotuning, or automatic tuning, means that the controller is tuned automatically. Autotuning is normally applied to PID controllers, but the technique can also be used to initialize more advanced controllers. The main approaches to autotuning are based on step response analysis or frequency response analysis obtained using relay feedback. Autotuning has been well received in industry, and today most distributed control systems have some kind of autotuning technique.

Keywords

Automatic tuning; Gain scheduling; PID control; Process control; Proportional-integral-derivative control; Relay feedback

Background

In the late 1970s and early 1980s, there was a quite rapid change of controller implementation in process control. The analog controllers were replaced by computer-based controllers and distributed control systems. The functionality of the new controllers was often more or less a copy of the old analog equipment, but new functions that utilized the computer implementation were gradually introduced. One of the first functions of this type was autotuning. Autotuning is a method to tune the controllers, normally PID controllers, automatically.

What Is Autotuning?

A PID controller in its basic form has the structure

$$u(t) = K\left(e(t) + \frac{1}{T_i}\int_0^t e(\tau)d\tau + T_d\frac{d}{dt}e(t)\right),$$

where u is the controller output and $e = y_{sp} - y$ is the control error, where y_{sp} is the setpoint and y is the process output. There are three parameters in the controller, gain K, integral time T_i, and derivative time T_d. These parameters have to be set by the user. Their values are dependent of the process dynamics and the specifications of the control loop.

A process control plant may have thousands of control loops, which means that maintaining high-performance controller tuning can be very time consuming. This was the main reason why procedures for automatic tuning were installed so rapidly in the computer-based controllers.

When a controller is to be tuned, the following steps are normally performed by the user:
1. To determine the process dynamics, a minor disturbance is injected by changing the control signal.
2. By studying the response in the process output, the process dynamics can be determined, i.e., a process model is derived.
3. The controller parameters are finally determined based on the process model and the specifications.

Autotuning means simply that these three steps are performed automatically. Instead of having a human to perform these tasks, they are performed automatically on demand from the user. Ideally, the autotuning should be fully automatic, which means that no information about the process dynamics is required from the user.

Automatic tuning can be performed in many ways. The process disturbance can take different forms, e.g., in the form of step changes or some kind of oscillatory excitation. The model obtained can be more or less accurate. There are also many ways to tune the controller based on the process model.

Here, we will discuss two main approaches for autotuning, namely, those that are based on step response analysis and those that are based on frequency response analysis.

Methods Based on Step Response Analysis

Most methods for automatic tuning of PID controllers are based on step response analysis. When the operator wishes to tune the controller, an open-loop step response experiment is performed. A process model is then obtained from the step response, and controller parameters are determined. This is usually done using simple formulas or look-up tables.

The most common process model used for PID controller tuning based on step response experiments is the first-order plus dead-time model

$$G(s) = \frac{K_p}{1 + sT}e^{-sL}$$

where K_p is the static gain, T is the apparent time constant, and L is the apparent dead time. These three parameters can be obtained from a step response experiment according to Fig. 1.

Static gain K_p is given by the ratio between the steady-state change in process output and the magnitude of the control signal step, $K_p = \Delta y/\Delta u$. Dead-time L is determined from the time elapsed from the step change to the intersection of the largest slope of the process output with the level of the process output before the step change. Finally, time constant T is the time when the process output has reached 63 % of its final value, subtracted by L.

Autotuning, Fig. 1 Determination of K_p, L, and T from a step response experiment

The greatest difficulty in carrying out tuning automatically is in selecting the amplitude of the step. The user naturally wants the disturbance to be as small as possible so that the process is not disturbed more than necessary. On the other hand, it is easier to determine the process model if the disturbance is large. The result of this dilemma is usually that the user has to decide how large the step in the control signal should be. Another problem is to determine when the step response has reached its final value.

Methods Based on Frequency Response Analysis

Frequency-domain characteristics of the process can be obtained by adding sinusoidals to the control signal, but without knowing the frequency response of the process, the interesting frequency range and acceptable amplitudes are not known. A method that automatically provides a relevant frequency response can be determined from experiments with relay feedback according to Fig. 2. Notice that there is a switch that selects either relay feedback or ordinary PID feedback. When it is desired to tune the system, the PID function is disconnected and the system is connected to relay feedback control. Relay feedback control is the same as on/off control, but where the on and off levels are carefully chosen and not 0 and 100 %. The relay feedback makes the control loop oscillate. The period and the amplitude of the oscillation is determined when steady-state oscillation is obtained. This gives the ultimate period and the ultimate gain. The parameters of a PID controller can then be determined from these values. The PID controller is then automatically switched in again, and the control is executed with the new PID parameters.

For large classes of processes, relay feedback gives an oscillation with period close to the ultimate frequency ω_u, as shown in Fig. 3, where the control signal is a square wave and the process output is close to a sinusoid. The gain of the transfer function at this frequency is also easy to obtain from amplitude measurements.
Autotuning, Fig. 2 The relay autotuner. In the tuning mode the process is connected to relay feedback

Describing function analysis can be used to determine the process characteristics. The describing function of a relay with hysteresis is

$$N(a) = \frac{4d}{\pi a} \left(\sqrt{1 - \left(\frac{\epsilon}{a}\right)^2} - i\,\frac{\epsilon}{a} \right)$$

where d is the relay amplitude, ϵ the relay hysteresis, and a the amplitude of the input signal. The negative inverse of this describing function is a straight line parallel to the real axis; see Fig. 4. The oscillation corresponds to the point where the negative inverse describing function crosses the Nyquist curve of the process, i.e., where

$$G(i\omega) = -\frac{1}{N(a)}$$

Since $N(a)$ is known, $G(i\omega)$ can be determined from the amplitude a and the frequency ω of the oscillation.

Notice that the relay experiment is easily automated. There is often an initialization phase where the noise level in the process output is determined during a short period of time. The noise level is used to determine the relay hysteresis and a desired oscillation amplitude in the process output. After this initialization phase, the relay function is introduced. Since the amplitude of the oscillation is proportional to the relay output, it is easy to control it by adjusting the relay output.

Different Adaptive Techniques

In the late 1970s, at the same time as autotuning procedures were developed and implemented in industrial controllers, there was a large academic interest in adaptive control. These two concepts
Autotuning, Fig. 3 Process output y and control signal u during relay feedback
Autotuning, Fig. 4 The negative inverse describing function of a relay with hysteresis $-1/N(a)$ and a Nyquist curve $G(i\omega)$

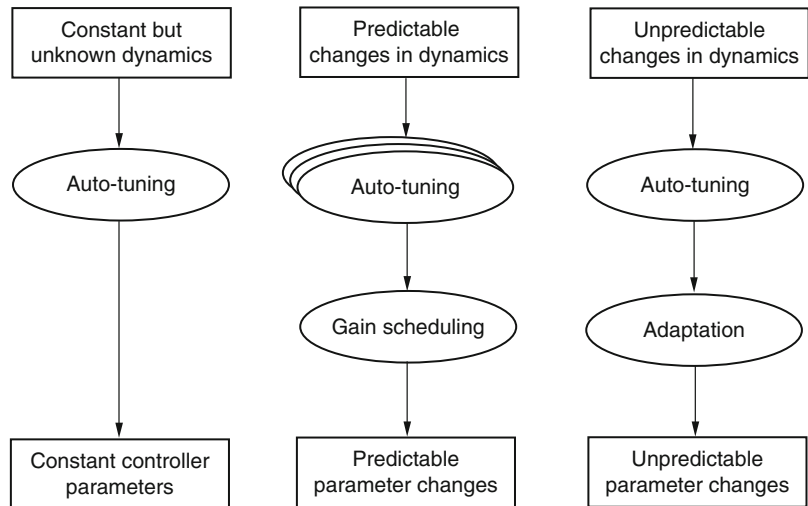
are often mixed up with each other. Autotuning is sometimes called tuning on demand. An identification experiment is performed, controller parameters are determined, and the controller is then run with fixed parameters. An adaptive controller is, however, a controller where the controller parameters are adjusted online based on information from routine data. Automatic tuning and adaptive control have, however, one thing in common, namely, that they are methods to adapt the controller parameters to the actual process

dynamics. Therefore, they are both called *adaptive techniques*.

There is a third adaptive technique, namely, gain scheduling. Gain scheduling is a system where controller parameters are changed depending on measured operating conditions. The scheduling variable can, for instance, be the measurement signal, controller output, or an external signal. For historical reasons the word gain scheduling is used even if other parameters like integral time or derivative time are changed. Gain scheduling is a very effective way of controlling systems whose dynamics change with the operating conditions. Automatic tuning has made it possible to generate gain schedules automatically.

Although research on adaptive techniques has almost exclusively focused on adaptation, experience has shown that autotuning and gain scheduling have much wider industrial applicability. Figure 5 illustrates the appropriate use of the different techniques.

Controller performance is the first issue to consider. If requirements are modest, a controller with constant parameters and conservative tuning can be used. Other solutions should be considered when higher performance is required.

Autotuning, Fig. 5 When to use different adaptive techniques


If the process dynamics are constant, a controller with constant parameters should be used. The parameters of the controller can be obtained by autotuning.

If the process dynamics or the character of the disturbances are changing, it is useful to compensate for these changes by changing the controller. If the variations can be predicted from measured signals, gain scheduling should be used since it is simpler and gives superior and more robust performance than continuous adaptation. Typical examples are variations caused by nonlinearities in the control loop. Autotuning can be used to build up the gain schedules automatically.

There are also cases where the variations in process dynamics are not predictable. Typical examples are changes due to unmeasurable variations in raw material, wear, fouling, etc. These variations cannot be handled by gain scheduling but must be dealt with by adaptation. An autotuning procedure is often used to initialize the adaptive controller. It is then sometimes called pre-tuning or initial tuning.

To summarize, autotuning is a key component in all adaptive techniques and a prerequisite for their use in practice.

Industrial Products

Commercial PID controllers with adaptive techniques have been available since the beginning of the late 1970s, both in single-station controllers and in distributed control systems.

Two important, but distinct, applications of PID autotuners are *temperature controllers* and *process controllers*. Temperature controllers are primarily designed for temperature control, whereas process controllers are supposed to work for a wide range of control loops in the process industry such as flow, pressure, level, temperature, and concentration control loops. Automatic tuning is easier to implement in temperature controllers, since most temperature control loops have several common features. This is the main reason why automatic tuning was introduced more rapidly in these controllers.

Since the processes that are controlled with process controllers may have large differences in their dynamics, tuning becomes more difficult compared to the pure temperature control loops.

Automatic tuning can also be performed by external devices which are connected to the control loop during the tuning phase. Since these devices are supposed to work together with controllers from different manufacturers, they must

be provided with quite a lot of information about the controller structure and parameterization in order to provide appropriate controller parameters. Such information includes signal ranges, controller structure (series or parallel form), sampling rate, filter time constants, and units of the different controller parameters (gain or proportional band, minutes or seconds, time or repeats/time).

Summary and Future Directions

Most of the autotuning methods that are available in industrial products today were developed about 30 years ago, when computer-based controllers started to appear. These autotuners are often based on simple models and simple tuning rules. With the computer power available today, and the increased knowledge about PID controller design, there is a potential for improving the autotuners, and more efficient autotuners will probably appear in industrial products quite soon.

Averaging Algorithms and Consensus

Wei Ren
Department of Electrical Engineering,
University of California, Riverside, CA, USA

A

Abstract

In this article, we overview averaging algorithms and consensus in the context of distributed coordination and control of networked systems. The two subjects are closely related but not identical. Distributed consensus means that a team of agents reaches an agreement on certain variables of interest by interacting with their neighbors. Distributed averaging aims at computing the average of certain variables of interest among multiple agents by local communication. Hence averaging can be treated as a special case of consensus – average consensus. For distributed consensus, we introduce distributed algorithms for agents with single-integrator, general linear, and nonlinear dynamics. For distributed averaging, we introduce static and dynamic averaging algorithms. The former is useful for computing the average of initial conditions (or constant signals), while the latter is useful for computing the average of time-varying signals. Future research directions are also discussed.

Keywords

Cooperative control; Coordination; Distributed control; Multi-agent systems; Networked systems

Introduction

In the area of control of networked systems, low cost, high adaptivity and scalability, great robustness, and easy maintenance are critical factors.

To achieve these factors, distributed coordination and control algorithms that rely on only local interaction between neighboring agents to achieve collective group behavior are more favorable than centralized ones. In this article, we overview averaging algorithms and consensus in the context of distributed coordination and control of networked systems.

Distributed consensus means that a team of agents reaches an agreement on certain variables of interest by interacting with their neighbors. A consensus algorithm is an update law that drives the variables of interest of all agents in the network to converge to a common value (Jadbabaie et al. 2003; Olfati-Saber et al. 2007; Ren and Beard 2008). Examples of the variables of interest include a local representation of the center and shape of a formation, the rendezvous time, the length of a perimeter being monitored, the direction of motion for a multi-vehicle swarm, and the probability that a target has been identified. Consensus algorithms have applications in rendezvous, formation control, flocking, attitude alignment, and sensor networks (Bai et al. 2011a; Bullo et al. 2009; Mesbahi and Egerstedt 2010; Qu 2009; Ren and Cao 2011). Distributed averaging algorithms aim at computing the average of certain variables of interest among multiple agents by local communication. Distributed averaging finds applications in distributed computing, distributed signal processing, and distributed optimization (Tsitsiklis et al. 1986). Hence the variables of interest are dependent on the applications (e.g., a sensor measurement or a network quantity). Consensus and averaging algorithms are closely connected and yet nonidentical. When all agents are able to compute the average, they essentially reach a consensus, the so-called average consensus. On the other hand, when the agents reach a consensus, the consensus value might or might not be the average value.

Graph Theory Notations. Suppose that there are n agents in a network. A *network topology* (equivalently, *graph*) $\mathcal{G}$ consisting of a node set $\mathcal{V} = \{1, \ldots, n\}$ and an edge set $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ will be used to model *interaction* (communication or sensing) between the n agents. An *edge* (i, j) in

a *directed graph* denotes that agent j can obtain information from agent i, but not necessarily vice versa. In contrast, an edge (i, j) in an *undirected graph* denotes that agents i and j can obtain information from each other. Agent j is a *(in-) neighbor* of agent i if $(j, i) \in \mathcal{E}$. Let $\mathcal{N}_i$ denote the neighbor set of agent i. We assume that $i \in \mathcal{N}_i$. A *directed path* is a sequence of edges in a directed graph of the form $(i_1, i_2), (i_2, i_3), \ldots$, where $i_j \in \mathcal{V}$. An *undirected path* in an undirected graph is defined analogously. A directed graph is *strongly connected* if there is a directed path from every agent to every other agent. An undirected graph is *connected* if there is an undirected path between every pair of distinct agents. A directed graph *has a directed spanning tree* if there exists at least one agent that has directed paths to all other agents. For example, Fig. 1 shows a directed graph that has a directed spanning but is not strongly connected. The *adjacency matrix* $\mathcal{A} = [a_{ij}] \in \mathbb{R}^{n \times n}$ associated with $\mathcal{G}$ is defined such that a_{ij} (the weight of edge (j, i)) is positive if agent j is a neighbor of agent i while $a_{ij} = 0$ otherwise. The (nonsymmetric) *Laplacian matrix* (Agaev and Chebotarev 2005) $\mathcal{L} = [\ell_{ij}] \in \mathbb{R}^{n \times n}$ associated with $\mathcal{A}$ and hence $\mathcal{G}$ is defined as $\ell_{ii} = \sum_{j \neq i} a_{ij}$ and $\ell_{ij} = -a_{ij}$ for all $i \neq j$. For an undirected graph, we assume that $a_{ij} = a_{ji}$. A graph is *balanced* if for every agent the total edge weights of its incoming links is equal to the total edge weights of its outgoing links ($\sum_{j=1}^{n} a_{ij} = \sum_{j=1}^{n} a_{ji}$ for all i).
Averaging Algorithms and Consensus, Fig. 1 A directed graph that characterizes the interaction among five agents, where A_i, $i = 1, \ldots, 5$, denotes agent i. An *arrow* from agent j to agent i indicates that agent i receives information from agent j. The directed graph has a directed spanning tree but is not strongly connected. Here both agents 1 and 2 have directed paths to all other agents

Consensus

Consensus has a long history in management science, statistical physics, and distributed computing and finds recent interests in distributed control. While in the area of distributed control of networked systems the term *consensus* was initially more or less dominantly referred to the case of a continuous-time version of a distributed linear averaging algorithm, such a term has been broadened to a great extent later on. Related problems to consensus include synchronization, agreement, and rendezvous. The study of consensus can be categorized in various manners. For example, in terms of the final consensus value, the agents could reach a consensus on the average, a weighted average, the maximum value, the minimum value, or a general function of their initial conditions, or even a (changing) state that serves as a reference. A consensus algorithm could be linear or nonlinear. Consensus algorithms can be designed for agents with linear or nonlinear dynamics. As the agent dynamics become more complicated, so do the algorithm design and analysis. Numerous issues are also involved in consensus such as network topologies (fixed vs. switching, deterministic vs. random, directed vs. undirected, asynchronous vs. synchronous), time delay, quantization, optimality, sampling effects, and convergence speed. For example, in real applications, due to nonuniform communication/sensing ranges or limited field of view of sensors, the network topology could be directed rather than undirected. Also due to unreliable communication/sensing and limited communication/sensing ranges, the network topology could be switching rather than fixed.

Consensus for Agents
with Single-Integrator Dynamics

We start with a fundamental consensus algorithm for agents with single-integrator dynamics. The results in this section follow from Jadbabaie et al. (2003), Olfati-Saber et al. (2007), Ren and Beard (2008), Moreau (2005), and Agaev and Chebotarev (2000). Consider agents with single-integrator dynamics

$$\dot{x}_i(t) = u_i(t), \quad i = 1, \ldots, n, \qquad (1)$$

where x_i is the state and u_i is the control input. A common consensus algorithm for (1) is

$$u_i(t) = \sum_{j \in \mathcal{N}_i(t)} a_{ij}(t)[x_j(t) - x_i(t)], \quad (2)$$

where $\mathcal{N}_i(t)$ is the neighbor set of agent i at time t and $a_{ij}(t)$ is the (i, j) entry of the adjacency matrix $\mathcal{A}$ of the graph $\mathcal{G}$ at time t. A consequence of (2) is that the state $x_i(t)$ of agent i is driven toward the states of its neighbors or equivalently toward the weighted average of its neighbors' states. The closed-loop system of (1) using (2) can be written in matrix form as

$$\dot{x}(t) = -\mathcal{L}(t)x(t), \qquad (3)$$

where x is a column stack vector of all x_i and $\mathcal{L}$ is the Laplacian matrix. Consensus is *reached* if for all initial states, the agents' states eventually become identical. That is, for all $x_i(0)$, $\|x_i(t) - x_j(t)\|$ approaches zero eventually.

The properties of the Laplacian matrix $\mathcal{L}$ play an important role in the analysis of the closed-loop system (3). When the graph $\mathcal{G}$ (and hence the associated Laplacian matrix $\mathcal{L}$) is fixed, (3) can be analyzed by studying the eigenvalues and eigenvectors of $\mathcal{L}$. Due to its special structure, for any graph $\mathcal{G}$, the associated Laplacian matrix $\mathcal{L}$ has at least one zero eigenvalue with an associated right eigenvector $\mathbf{1}$ (column vector of all ones) and all other eigenvalues have positive real parts. To ensure consensus, it is equivalent to ensure that $\mathcal{L}$ has a simple zero eigenvalue. It can be shown that the following three statements are equivalent: (i) the agents reach a consensus exponentially for arbitrary initial states; (ii) the graph $\mathcal{G}$ has a directed spanning tree; and (iii) the Laplacian matrix $\mathcal{L}$ has a simple zero eigenvalue with an associated right eigenvector $\mathbf{1}$ and all other eigenvalues have positive real parts. When consensus is reached, the final consensus value is a weighted average of the initial states of those agents that have directed paths to all other agents (see Fig. 2 for an illustration).

Averaging Algorithms and Consensus, Fig. 2 Consensus for five agents using the algorithm (2) for (1). Here the graph $\mathcal{G}$ is given by Fig. 1. The initial states are chosen as $x_i(0) = 2i$, where $i = 1, \ldots, 5$. Consensus is reached as $\mathcal{G}$ has a directed spanning tree. The final consensus value is a weighted average of the initial states of agents 1 and 2
When the graph $\mathcal{G}(t)$ is switching at time instants $t_0, t_1, \ldots$, the solution to the closed-loop system (3) is given by $x(t) = \Phi(t, 0)x(0)$, where $\Phi(t, 0)$ is the transition matrix corresponding to $-\mathcal{L}(t)$. Consensus is reached if $\Phi(t, 0)$ eventually converges to a matrix with identical rows. Here $\Phi(t, 0) = \Phi(t, t_k)\Phi(t_k, t_{k-1}) \cdots \Phi(t_1, 0)$, where $\Phi(t_k, t_{k-1})$ is the transition matrix corresponding to $\mathcal{L}(t)$ at time interval $[t_{k-1}, t_k]$. It turns out that each transition matrix is a *row-stochastic* matrix with positive diagonal entries. A square matrix is row stochastic if all its entries are nonnegative and all of its row sums are one. The consensus convergence can be analyzed by studying the product of row-stochastic matrices. Another analysis technique is a Lyapunov approach (e.g., $\max x_i - \min x_i$). It can be shown that the agents' states reach a consensus if there exists an infinite sequence of contiguous, uniformly bounded time intervals, with the property that across each such interval, the union of the graphs $\mathcal{G}(t)$ has a directed spanning tree. That is, across each such interval, there exists at least one agent that can directly or indirectly influence all other agents. It is also possible to achieve certain nice features by designing nonlinear consensus algorithms of the form $u_i(t) = \sum_{j \in \mathcal{N}_i(t)} a_{ij}(t)\psi[x_j(t) - x_i(t)]$, where $\psi(\cdot)$ is a nonlinear function satisfying certain properties. One example is a continuous nondecreasing odd function. For example, a saturation type function could be introduced to

account for actuator saturation and a signum type function could be introduced to achieve finite-time convergence.

As shown above, for single-integrator dynamics, the consensus convergence is determined entirely by the network topologies. The primary reason is that the single-integrator dynamics are internally stable. However, when more complicated agent dynamics are involved, the consensus algorithm design and analysis become more complicated. On one hand, whether the graph is undirected (respectively, switching) or not has significant influence on the complexity of the consensus analysis. On the other hand, not only the network topology but also the agent dynamics themselves and the parameters in the consensus algorithm play important roles. Next we introduce consensus for agents with general linear and nonlinear dynamics.

Consensus for Agents with General Linear Dynamics

In some circumstances, it is relevant to deal with agents with general linear dynamics, which can also be regarded as linearized models of certain nonlinear dynamics. The results in this section follow from Li et al. (2010). Consider agents with general linear dynamics

$$\dot{x}_i = Ax_i + Bu_i, \quad y_i = Cx_i, \qquad (4)$$

where $x_i \in \mathbb{R}^m$, $u_i \in \mathbb{R}^p$, and $y_i \in \mathbb{R}^q$ are, respectively, the state, the control input, and the output of agent i and A, B, C are constant matrices with compatible dimensions.

When each agent has access to the relative states between itself and its neighbors, a distributed static consensus algorithm is designed for (4) as

$$u_i = cK \sum_{j \in \mathcal{N}_i} a_{ij}(x_i - x_j), \qquad (5)$$

where $c > 0$ is a coupling gain, $K \in \mathbb{R}^{p \times m}$ is the feedback gain matrix, and $\mathcal{N}_i$ and a_{ij} are defined as in (2). It can be shown that if the graph $\mathcal{G}$ has a directed spanning tree, consensus is reached using (5) for (4) if and only if all the matrices $A + c\lambda_i(\mathcal{L})BK$, where $\lambda_i(\mathcal{L}) \neq 0$ are Hurwitz. Here $\lambda_i(\mathcal{L})$ denotes the ith eigenvalue of the Laplacian matrix $\mathcal{L}$. A necessary condition for reaching a consensus is that the pair (A, B) is stabilizable. The consensus algorithm (5) can be designed via two steps:

(a) Solve the linear matrix inequality $A^T P + PA - 2BB^T < 0$ to get a positive-definite solution P. Then let the feedback gain matrix $K = -B^T P^{-1}$.
(b) Select the coupling strength c larger than the threshold value $1/ \min_{\lambda_i(\mathcal{L}) \neq 0} \mathrm{Re}[\lambda_i(\mathcal{L})]$, where $\mathrm{Re}(\cdot)$ denotes the real part.

Note that here the threshold value depends on the eigenvalues of the Laplacian matrix, which is in some sense global information. To overcome such a limitation, it is possible to introduce adaptive gains in the algorithm design. The gains could be updated dynamically using local information.

When the relative states between each agent and its neighbors are not available, one is motivated to make use of the output information and employ observer-based design to estimate the relative states. An observer-type consensus algorithm is designed for (4) as

$$\dot{v}_i = (A + BF)v_i + cL \sum_{j \in \mathcal{N}_i} a_{ij}[C(v_i - v_j) - (y_i - y_j)],$$
$$u_i = Fv_i, \quad i = 1, \cdots, n, \qquad (6)$$

where $v_i \in \mathbb{R}^m$ are the observer states, $F \in \mathbb{R}^{p \times n}$ and $L \in \mathbb{R}^{m \times q}$ are the feedback gain matrices, and $c > 0$ is a coupling gain. Here the algorithm (6) uses not only the relative outputs between each agent and its neighbors but also its own and neighbors' observer states. While relative outputs could be obtained through local measurements, the neighbors' observer states can only be obtained via communication. It can be shown that if the graph $\mathcal{G}$ has a directed spanning tree, consensus is reached using (6) for (4) if the matrices $A + BF$ and $A + c\lambda_i(\mathcal{L})LC$, where $\lambda_i(\mathcal{L}) \neq 0$, are Hurwitz. The observer-type consensus algorithm (6) can be seen as an extension of the single-system observer design to multi-agent systems. Here the *separation principle* of the traditional observer design still holds in the multi-agent setting in the sense that the feedback gain matrices F and L can be designed separately.

Consensus for Agents with Nonlinear Dynamics

In multi-agent applications, agents usually represent physical vehicles with special dynamics, especially nonlinear dynamics for the most part. Examples include Lagrangian systems for robotic manipulators and autonomous robots, nonholonomic systems for unicycles, attitude dynamics for rigid bodies, and general nonlinear systems. Similar to the consensus algorithms for linear multi-agent systems, the consensus algorithms used for these nonlinear agents are often designed based on state differences between each agent and its neighbors. But due to the inherent nonlinearity, the problem is more complicated and additional terms might be required in the algorithm design. The main techniques used in the consensus analysis for nonlinear multi-agent systems are often Lyapunov-based techniques (Lyapunov functions, passivity theory, nonlinear contraction analysis, and potential functions).

Early results on consensus for agents with nonlinear dynamics primarily focus on undirected graphs to exploit the symmetry to facilitate the construction of Lyapunov function candidates. Unfortunately, the extension from an undirected graph to a directed one is nontrivial.

For example, the directed graph does not preserve the passivity properties in general. Moreover, the directed graph could cause difficulties in the design of (positive-definite) Lyapunov functions. One approach is to integrate the nonnegative left eigenvector of the Laplacian matrix associated with the zero eigenvalue into the Lyapunov function, which is valid for strongly connected graphs and has been applied in some problems. Another approach is based on sliding mode control. The idea is to design a sliding surface for reaching a consensus. Taking multiple Lagrangian systems as an example, the agent dynamics are represented by

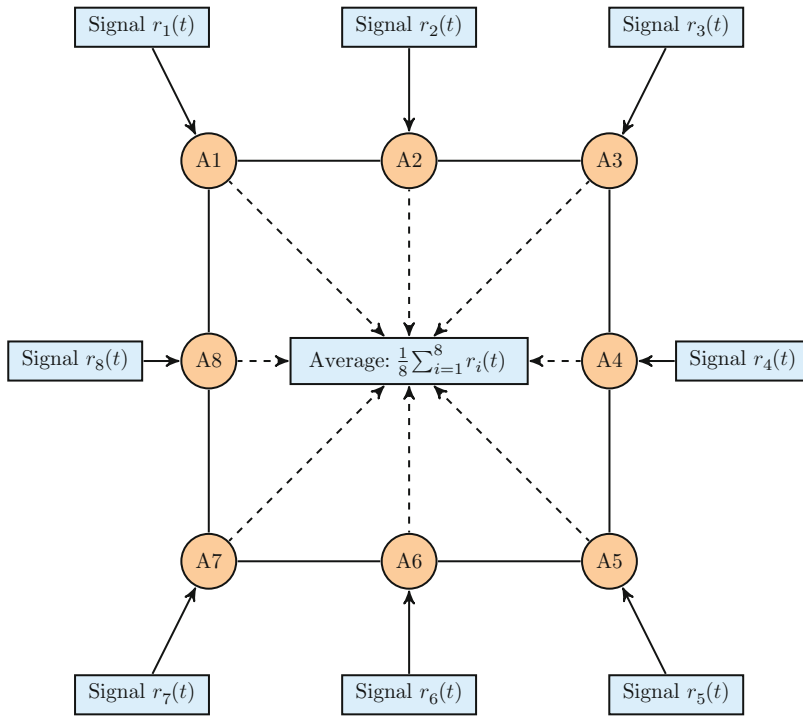
$$M_i(q_i)\ddot{q}_i + C_i(q_i, \dot{q}_i)\dot{q}_i + g_i(q_i) = \tau_i,$$
$$i = 1, \cdots, n, \tag{7}$$

where $q_i \in \mathbb{R}^p$ is the vector of generalized coordinates, $M_i(q_i) \in \mathbb{R}^{p \times p}$ is the symmetric positive-definite inertia matrix, $C_i(q_i, \dot{q}_i)\dot{q}_i \in \mathbb{R}^p$ is the vector of Coriolis and centrifugal torques, $g_i(q_i) \in \mathbb{R}^p$ is the vector of gravitational torque, and $\tau_i \in \mathbb{R}^p$ is the vector of control torque on the ith agent. The sliding surface can be designed as

$$s_i = \dot{q}_i - \dot{q}_{ri} = \dot{q}_i + \alpha \sum_{j \in \mathcal{N}_i} a_{ij}(q_i - q_j) \tag{8}$$

where α is a positive scalar. Note that when $s_i = 0$, (8) is actually the closed-loop system of a consensus algorithm for single integrators. Then if the control torque τ_i can be designed using only local information from neighbors to drive s_i to zero, consensus will be reached as s_i can be treated as a vanishing disturbance to a system that reaches consensus exponentially.

It is generally very challenging to deal with general directed or switching graphs for agents with more complicated dynamics other than single-integrator dynamics. In some cases, the challenge could be overcome by introducing and updating additional auxiliary variables (often observer-based algorithms) and exchanging these variables between neighbors (see, e.g., (6)). In the algorithm design, the agents might use not only relative physical states between

neighbors but also local auxiliary variables from neighbors. While relative physical states could be obtained through sensing, the exchange of auxiliary variables can only be achieved by communication. Hence such generalization is obtained at the price of increased communication between the neighboring agents. Unlike some other algorithms, it is generally impossible to implement the algorithm relying on purely relative sensing between neighbors without the need for communication.


Averaging Algorithms

Existing distributed averaging algorithms are primarily static averaging algorithms based on linear local average iterations or gossip iterations. These algorithms are capable of computing the average of the initial conditions of all agents (or constant signals) in a network. In particular, the linear local-average-iteration algorithms are usually synchronous, where at each iteration each agent repeatedly updates its state to be the average of those of its neighbors. The gossip algorithms are asynchronous, where at each iteration a random pair of agents are selected to exchange their states and update them to be the average of the two. Dynamic averaging algorithms are of significance when there exist time-varying signals. The objective is to compute the average of these time-varying signals in a distributed manner.

Static Averaging
Take a linear local-average-iteration algorithm as an example. The results in this section follow from Tsitsiklis et al. (1986), Jadbabaie et al. (2003), and Olfati-Saber et al. (2007). Let x_i be the information state of agent i. A linear local-average-iteration-type algorithm has the form

$$x_i[k + 1] = \sum_{j \in \mathcal{N}_i[k]} a_{ij}[k]x_j[k], \quad i = 1, \ldots, n, \tag{9}$$

where k denotes a communication event, $\mathcal{N}_i[k]$ denotes the neighbor set of agent i, and $a_{ij}[k]$ is the (i, j) entry of the adjacency matrix $\mathcal{A}$ of the graph $\mathcal{G}$ that represents the communication

Averaging Algorithms and Consensus, Fig. 3 Illustration of distributed averaging of multiple (time-varying) signals. Here A_i denotes agent i and $r_i(t)$ denotes a (time-varying) signal associated with agent i. Each agent needs to compute the average of all agents' signals but can communicate with only its neighbors

topology at time k, with the additional assumption that $\mathcal{A}$ is row stochastic and $a_{ii}[k] > 0$ for all $i = 1, \ldots, n$. Intuitively, the information state of each agent is updated as the weighted average of its current state and the current states of its neighbors at each iteration. Note that an agent maintains its current state if it does not exchange information with other agents at that event instant. In fact, a discretized version of the closed-loop system of (1) using (2) (with a sufficiently small sampling period) takes in the form of (9). The objective here is for all agents to compute the average of their initial states by communicating with only their neighbors. That is, each $x_i[k]$ approaches $\frac{1}{n}\sum_{j=1}^{n} x_j[0]$ eventually. To compute the average of multiple constant signals c_i, we could simply set $x_i[0] = c_i$. The algorithm (9) can be written in matrix form as $x[k+1] = \mathcal{A}[k]x[k]$, where x is a column stack vector of all x_i and $\mathcal{A}[k] = [a_{ij}[k]]$ is a row-stochastic matrix.

When the graph $\mathcal{G}$ (and hence the matrix $\mathcal{A}$) is fixed, the convergence of the algorithm (9) can be analyzed by studying the eigenvalues and eigenvectors of the row-stochastic matrix $\mathcal{A}$. Because all diagonal entries of $\mathcal{A}$ are positive, Gershgorin's disc theorem implies that all eigenvalues of $\mathcal{A}$ are either within the open unit disk or at one. When the graph $\mathcal{G}$ is strongly connected, the Perron-Frobenius theorem implies that $\mathcal{A}$ has a simple eigenvalue at one with an associated right eigenvector $\mathbf{1}$ and an associated positive left eigenvector. Hence when $\mathcal{G}$ is strongly connected, it turns out that $\lim_{k\to\infty} \mathcal{A}^k = \mathbf{1}v^T$, where v^T is a positive left eigenvector of $\mathcal{A}$ associated with the eigenvalue one and satisfies $v^T\mathbf{1} = 1$. Note that $x[k] = \mathcal{A}^k x[0]$. Hence, each agent's state $x_i[k]$ approaches $v^T x[0]$ eventually. If it can be further ensured that $v = \frac{1}{n}\mathbf{1}$, then averaging is achieved. It can be shown that the agents' states converge to the average of their initial values if and only if the directed graph $\mathcal{G}$ is both strongly connected and balanced or the undirected graph $\mathcal{G}$ is connected. When the graph is switching, the convergence of the algorithm (9) can be analyzed by studying the

product of row-stochastic matrices. Such analysis is closely related to Markov chains. It can be shown that the agents' states converge to the average of their initial values if the directed graph $\mathcal{G}$ is balanced at each communication event and strongly connected in a joint manner or the undirected graph $\mathcal{G}$ is jointly connected.

Dynamic Averaging

In a more general setting, there exist n time-varying signals, $r_i(t)$, $i = 1, \ldots, n$, which could be an external signal or an output from a dynamical system. Here $r_i(t)$ is available to only agent i and each agent can exchange information with only its neighbors. Each agent maintains a local estimate, denoted by $x_i(t)$, of the average of all the signals $\bar{r}(t) \triangleq \frac{1}{n} \sum_{k=1}^{n} r_k(t)$. The objective is to design a distributed algorithm for agent i based on $r_i(t)$ and $x_j(t)$, $j \in \mathcal{N}_i(t)$, such that all agents will finally track the average that changes over time. That is, $\|x_i(t) - \bar{r}(t)\|$, $i = 1, \ldots, n$, approaches zero eventually. Such a dynamic averaging idea finds applications in distributed sensor fusion with time-varying measurements (Bai et al. 2011b; Spanos and Murray 2005) and distributed estimation and tracking (Yang et al. 2008).

Figure 3 illustrates the dynamic averaging idea. If there exists a central station that can always access the signals of all agents, then it is trivial to compute the average. Unfortunately, in a distributed context, where there does not exist a central station and each agent can only communicate with its local neighbors, it is challenging for each agent to compute the average that changes over time. While each agent could compute the average of its own and local neighbors' signals, this will not be the average of all signals.

When the signal $r_i(t)$ can be arbitrary but its derivative exists and is bounded almost everywhere, a distributed nonlinear nonsmooth algorithm is designed in Chen et al. (2012) as

$$\dot{\phi}_i(t) = \alpha \sum_{j \in \mathcal{N}_i} \operatorname{sgn}[x_j(t) - x_i(t)]$$

$$x_i(t) = \phi_i(t) + r_i(t), \quad i = 1, \ldots, n, \quad (10)$$

where α is a positive scalar, $\mathcal{N}_i$ denotes the neighbor set of agent i, $\operatorname{sgn}(\cdot)$ is the signum function defined componentwise, ϕ_i is the internal state of the estimator with $\phi_i(0) = 0$, and x_i is the estimate of the average $\bar{r}(t)$. Due to the existence of the discontinuous signum function, the solution of (10) is understood in the Filippov sense (Cortes 2008).

The idea behind the algorithm (10) is as follows. First, (10) is designed to ensure that $\sum_{i=1}^{n} x_i(t) = \sum_{i=1}^{n} r_i(t)$ holds for all time. Note that $\sum_{i=1}^{n} x_i(t) = \sum_{i=1}^{n} \phi_i(t) + \sum_{i=1}^{n} r_i(t)$. When the graph $\mathcal{G}$ is undirected and $\phi_i(0) = 0$, it follows that $\sum_{i=1}^{n} \phi_i(t) = \sum_{i=1}^{n} \phi_i(0) + \alpha \sum_{i=1}^{n} \sum_{j \in \mathcal{N}_i} \int_0^t \operatorname{sgn}[x_j(\tau) - x_i(\tau)] d\tau = 0$. As a result, $\sum_{i=1}^{n} x_i(t) = \sum_{i=1}^{n} r_i(t)$ holds for all time. Second, when $\mathcal{G}$ is connected, if the algorithm (10) guarantees that all estimates x_i approach the same value in *finite time*, then it can be guaranteed that each estimate approaches the average of all signals in finite time.

Summary and Future Research Directions

Averaging algorithms and consensus play an important role in distributed control of networked systems. While there is significant progress in this direction, there are still numerous open problems. For example, it is challenging to achieve averaging when the graph is not balanced. It is generally not clear how to deal with a general directed or switching graph for nonlinear agents or nonlinear algorithms when the algorithms are based on only interagent physical state coupling without the need for communicating additional auxiliary variables between neighbors. The study of consensus for multiple underactuated agents remains a challenge. Furthermore, when the agents' dynamics are heterogeneous, it is challenging to design consensus algorithms. In addition, in the existing study, it is often assumed that the agents are cooperative. When there exist faulty or malicious agents, the problem becomes more involved.

BSDE

Abstract

A conditional expectation of the form $Y_t = E[\xi + \int_t^T f_s ds | \mathcal{F}_t]$ is regarded as a simple and typical example of backward stochastic differential equation (abbreviated by BSDE). BSDEs are widely applied to formulate and solve problems related to stochastic optimal control, stochastic games, and stochastic valuation.

Keywords

Brownian motion; Feynman-Kac formula; Lipschitz condition; Optimal stopping

Definition

A typical real valued backward stochastic differential equation defined on a time interval $[0, T]$ and driven by a d-dim. Brownian motion B is

$$\begin{cases} dY_t = -f(t, Y_t, Z_t)dt + Z_t dB_t, \\ Y_T = \xi, \end{cases}$$

or its integral form

$$Y_t = \xi + \int_t^T f(s, \omega, Y_s, Z_s)ds - \int_t^T Z_s dB_s, \tag{1}$$

where ξ is a given random variable depending on the (canonical) Brownian path $B_t(\omega) = \omega(t)$ on $[0, T]$, $f(t, \omega, y, z)$ is a given function of the time t, the Brownian path ω on $[0, t]$, and the pair of variables $(y, z) \in \mathbb{R}^m \times \mathbb{R}^{m \times d}$. A solution of this BSDE is a pair of stochastic processes (Y_t, Z_t), the solution of the above equation, on $[0, T]$ satisfying the following constraint: for each t, the value of $Y_t(\omega)$, $Z_t(\omega)$ depends only on the Brownian path ω on $[0, t]$. Notice that, because of this constraint, the extra freedom Z_t is needed. For simplicity we set $d = m = 1$.

Often square-integrable conditions for ξ and f and Lipschitz condition for f with respect to (y, z) are assumed under which there exists a unique square-integrable solution (Y_t, Z_t) on $[0, T]$ (existence and uniqueness theorem of BSDE). We can also consider a multidimensional process Y and/or a multidimensional Brownian motion B, L^p-integrable conditions ($p \geq 1$) for ξ and f, as well as local Lipschitz conditions of f with respect to (y, z). If Y_t is real valued, we often call the equation a real valued BSDE.

We compare this BSDE with the classical stochastic differential equation (SDE):

$$dX_s = \sigma(X_s)dB_s + b(X_s)ds$$

with given initial condition $X_s|_{s=0} = x \in \mathbb{R}^n$. Its integral form is

$$X_t(\omega) = x + \int_0^t \sigma(X_s(\omega))dB_s(\omega)$$
$$+ \int_0^t b(X_s(\omega))ds. \qquad (2)$$

Linear backward stochastic differential equation was firstly introduced (Bismut 1973) in stochastic optimal control problems to solve the adjoint equation in the stochastic maximum principle of Pontryagin's type. The above existence and uniqueness theorem was obtained by Pardoux and Peng (1990). In the research domain of economics, this type of 1-dimensional BSDE was also independently derived by Duffie and Epstein (1992). Comparison theorem of BSDE was obtained in Peng (1992) and improved in El Karoui et al. (1997a). Nonlinear Feynman-Kac formula was obtained in Peng (1991, 1992) and improved in Pardoux and Peng (1992). BSDE is applied as a nonlinear Black-Scholes option pricing formula in finance. This formulation was given in El Karoui et al. (1997b). We refer to a recent survey in Peng (2010) for more details.

Hedging and Risk Measuring in Finance

Let us consider the following hedging problem in a financial market with a typical model of continuous time asset price: the basic securities consist of two assets, a riskless one called bond, and a risky security called stock. Their prices are governed by $dP_t^0 = P_t^0 r dt$, for the bond, and

$$dP_t = P_t[b dt + \sigma dB_t], \text{ for the stock.}$$

Here we only consider the situation where the volatility rate $\sigma > 0$. The case of

multidimensional stocks with degenerate volatility matrix σ can be treated by constrained BSDE. Assume that a small investor whose investment behavior cannot affect market prices and who invests at time $t \in [0, T]$ the amount π_t of his or her wealth Y_t in the security and π_t^0 in the bond, thus $Y_t = \pi_t^0 + \pi_t$. If his investment strategy is self-financing, then we have $dY_t = \pi_t^0 dP_t^0/P_t^0 + \pi_t dP_t/P_t$, thus

$$dY_t = (rY_t + \pi_t\sigma\theta)dt + \pi_t\sigma dB_t,$$

where $\theta = \sigma^{-1}(b - r)$. A strategy $(Y_t, \pi_t)_{t \in [0,T]}$ is said to be feasible if $Y_t \geq 0$, $t \in [0, T]$. A European path-dependent contingent claim settled at time T is a given nonnegative function of path $\xi = \xi((P_t)_{t \in [0,T]})$. A feasible strategy (Y, π) is called a hedging strategy against a contingent claim ξ at the maturity T if it satisfies

$$dY_t = (rY_t + \pi_t\sigma\theta)dt + \pi_t\sigma dB_t, \quad Y_T = \xi.$$

This problem can be regarded as finding a stochastic control π and an initial condition Y_0 such that the final state replicates the contingent claim ξ, i.e., $Y_T = \xi$. This type of replications is also called "exact controllability" in terms of stochastic control (see Peng 2005 for more general results).

Observe that $(Y, \pi\sigma)$ is the solution of the above BSDE. It is called a superhedging strategy if there exists an increasing process K_t, often called an accumulated consumption process, such that

$$dY_t = (rY_t + \pi_t\sigma\theta)dt + \pi_t\sigma dB_t - dK_t, \quad Y_T = \xi.$$

This type of strategies is often applied in a constrained market in which certain constraint $(Y_t, \pi_t) \in \Gamma$ is imposed. In fact a real market has many frictions and constraints. An example is the common case where interest rate R for borrowing money is higher than the bond rate r. The above equation for the hedging strategy becomes

$$dY_t = [rY_t + \pi_t\sigma\theta - (R - r)(\pi_t - Y_t)^+]$$
$$dt + \pi_t\sigma dB_t, Y_T = \xi,$$

where $[\alpha]^+ = \max\{\alpha, 0\}$. A short selling constraint $\pi_t \geq 0$ is also a typical requirement in markets. The method of constrained BSDE can be applied to this type of problems. BSDE theory provides powerful tools to the robust pricing and risk measures for contingent claims (see El Karoui et al. 1997a). For the dynamic risk measure under Brownian filtration, see Rosazza Gianin (2006), Peng (2004), Barrieu and El Karoui (2005), Hu et al. (2005), and Delbaen et al. (2010).

Comparison Theorem

The comparison theorem, for a real valued BSDE, tells us that, if (Y_t, Z_t) and $(\bar{Y}_t, \bar{Z}_t)$ are two solutions of BSDE (1) with terminal condition $Y_T = \xi$, $\bar{Y}_T = \bar{\xi}$ such that $\xi(\omega) \geq \bar{\xi}(\omega)$, $\omega \in \Omega$, then one has $Y_t \geq \bar{Y}_t$. This theorem holds if f and ξ, $\bar{\xi}$ satisfy the abovementioned L^2-integrability condition and f is a Lipschitz function in (y, z). This theorem plays the same important role as the maximum principle in PDE theory. The theorem also has several very interesting generalizations (see Buckdahn et al. 2000).

Stochastic Optimization and Two-Person Zero-Sum Stochastic Games

An important point of view is to regard an expectation value as a solution of a special type of BSDE. Consider an optimal control problem

$$\min_u J(u): \quad J(u) = E\left[\int_0^T l(X_s, u_s)ds + h(X_T)\right].$$

Here the state process X is controlled by the control process u_t which is valued in a control (compact) domain U through the following d-dimensional SDE

$$dX_s = b(X_s, u_s)ds + \sigma(X_s)dB_s$$

defined in a Wiener probability space $(\Omega, \mathcal{F}, P)$ with the Brownian motion $B_t(\omega) = \omega(t)$ which is the canonical process. Here we only discuss the case $\sigma \equiv I_d$ for simplicity. Observe that in fact the expected value $J(u)$ is $Y_0^u = E[Y_0^u]$, where Y_t^u solves the BSDE

$$Y_t^u = h(X_T) + \int_t^T l(X_s, u_s)ds - \int_t^T Z_s^u dB_s.$$

From Girsanov transformation, under the probability measure $\tilde{P}$ defined by

$$\frac{d\tilde{P}}{dP}|_T = \exp\left\{\int_0^T b(X_s, u_s)dB_s - \frac{1}{2}\int_0^T |b(X_s, u_s, v_s)|^2 ds\right\}$$

X_t is a Brownian motion, and the above BSDE is changed to

$$Y_t^u = h(X_T) + \int_t^T [l(X_s, u_s) + \langle Z_s^u, b(X_s, u_s)\rangle]ds - \int_t^T Z_s^u dX_s,$$

where $\langle \cdot, \cdot \rangle$ is the Euclidean scalar product in $\mathbb{R}^d$. Notice that P and $\tilde{P}$ are absolutely continuous with each other. Compare this BSDE with the following one:

$$\hat{Y}_t = h(X_T) + \int_t^T H(X_s, \hat{Z}_s)ds - \int_t^T \hat{Z}_s dX_s, \tag{3}$$

where $H(x, z) := \inf_{u \in U} \{l(x, u) + \langle z, b(x, u)\rangle\}$. It is a direct consequence of the comparison theorem of BSDE that $\hat{Y}_0 \leq Y_0^u = J(u)$, for any admissible control u_t. Moreover, one can find a feedback control $\hat{u}$ such that $\hat{Y}_0 = J(\hat{u})$.

The above BSDE method has been introduced to solve the following two-person zero-sum game (Hamadène and Lepeltier 1995):

$$\max_v \min_u J(u, v), \quad J(u, v)$$
$$= E\left[\int_0^T l(X_s, u_s, v_s)ds + h(X_T)\right]$$

with

$$dX_s = b(X_s, u_s, v_s)ds + dB_s,$$

where (u_s, v_s) is formulated as above with compact control domains $u_s \in U$ and $v_s \in V$. In this case the equilibrium of the game exists if the following Isaac condition is satisfied:

$$H(x,z) := \max_{v \in V} \inf_{u \in U} \{l(x,u,v) + \langle z, b(x,u,v) \rangle\}$$
$$= \inf_{u \in U} \max_{v \in V} \{l(x,u,v) + \langle z, b(x,u,v) \rangle\},$$

and the equilibrium is also obtained through a BSDE (3) defined above.

Nonlinear Feynman-Kac Formula

A very interesting situation is when $f = g(X_t, y, z)$ and $Y_T = \varphi(X_T)$ in BSDE (1). In this case we have the following relation, called "nonlinear Feynman-Kac formula,"

$$Y_t = u(t, X_t), \quad Z_t = \sigma^T(X_t) \nabla u(t, X_t)$$

where $u = u(t, x)$ is the solution of the following quasilinear parabolic PDE:

$$\partial_t u + \mathcal{L} u + g(x, u, \sigma^T \nabla u) = 0, \qquad (4)$$

$$u(x, T) = \varphi(x), \qquad (5)$$

where $\mathcal{L}$ is the following, possibly degenerate, elliptic operator:

$$\mathcal{L}\varphi(x) = \frac{1}{2} \sum_{i,j=1}^{d} a_{ij}(x) \partial^2_{x_i x_j} \varphi(x)$$

$$+ \sum_{i=1}^{d} b_i(x) \partial_{x_i} \varphi(x), \quad a(x) = \sigma(x) \sigma^T(x).$$

Nonlinear Feynman-Kac formula can be used to solve a nonlinear PDE of form (4) to (5) by a BSDE (1) coupled with an SDE (2).

A general principle is, once we solve a BSDE driven by a Markov process X for which the terminal condition Y_T at time T depends only on X_T and the generator $f(t, \omega, y, z)$ also depends on the state X_t at each time t, then the corresponding solution of the BSDE is also state dependent, namely, $Y_t = u(t, X_t)$, where u is the solution

of the corresponding quasilinear PDE. Once Y_T and g are path functions of X, then the solution of the BSDE becomes also path dependent. In this sense, we can say that the PDE is in fact a "state-dependent BSDE,"and BSDE gives us a new generalization of "path-dependent PDE" of parabolic and/or elliptic types. This principle was illustrated in Peng (2010) for both quasilinear and fully nonlinear situations.

Observe that BSDE (1) and forward SDE (2) are only partially coupled. A fully coupled system of SDE and BSDE is called a forward-backward stochastic differential equation (FBSDE). It has the following form:

$$dX_t = b(t, X_t, Y_t, Z_t) dt + \sigma(t, X_t, Y_t, Z_t) dB_t,$$
$$X_0 = x \in \mathbb{R}^n,$$
$$-dY_t = f(t, X_t, Y_t, Z_t) dt - Z_t dB_t, \quad Y_T = \varphi(X_T).$$

In general the Lipschitz assumptions for b, σ, f, and φ w. r. t. (x, y, z) are not enough. Then Ma et al. (1994) have proposed a four-step scheme method of FBSDE for the nondegenerate Markovian case with σ independent of Z. For the case $\dim(x) = \dim(y) = n$, Hu and Peng (1995) proposed a new type of monotonicity condition. This method does not need to assume the coefficients to be deterministic. Peng and Wu (1999) have weakened the monotonicity condition. Observe that in the case where $b = \nabla_y H(x, y, z)$, $\sigma = \nabla_z H(x, y, z)$, and $f = \nabla_x H(x, y, z)$, for a given real valued function H convex in x concave in (y, z), the above FBSDE is called the stochastic Hamilton equation associated to a stochastic optimal control problem. We also refer to the book of Ma and Yong (1999) for a systematic exposition on this subject. For time-symmetric forward-backward stochastic differential equations and its relation with stochastic optimality, see Peng and Shi (2003) and Han et al. (2010).

Reflected BSDE and Optimal Stopping

If (Y, Z) solves the BSDE

$$dY_s = -g(s, Y_s, Z_s) ds + Z_s dB_s - dK_s, \quad Y_T = \xi,$$
$$(6)$$

where K is a càdlàg and increasing process with $K_0 = 0$ and $K_t \in L_P^2(\mathcal{F}_t)$, then Y or (Y, Z, K) is called a *supersolution* of the BSDE, or *g-supersolution*. This notion is often used for constrained BSDEs. A typical situation is as follows: for a given continuous adapted process $(L_t)_{t \in [0,T]}$, find a smallest g-supersolution (Y, Z, K) such that $Y_t \geq L_t$. This problem was initialed in El Karoui et al. (1997b). It is proved that this problem is equivalent to finding a triple (Y, Z, K) satisfying (4) and the following reflecting condition of Skorohod type:

$$Y_s \geq L_s, \quad \int_0^T (Y_s - L_s) dK_s = 0. \quad (7)$$

In fact $\tau^* := \inf\{t \in [0, T] : K_t > 0\}$ is the optimal stopping time associated to this BSDE. A well-known example is the pricing of American option.

Moreover, a new type of nonlinear Feynman-Kac formula was introduced: if all coefficients are given as in the formulation of the above nonlinear Feynman-Kac formula and $L_s = \Phi(X_s)$ where Φ satisfies the same condition as φ, then we have $Y_s = u(s, X_s)$, where $u = u(t, x)$ is the solution of the following variational inequality:

$$\min\{\partial_t u + \mathcal{L}u + g(x, u, \sigma^* Du), u - \Phi\}$$
$$= 0, \quad (t, x) \in [0, T] \times \mathbb{R}^n, \quad (8)$$

with terminal condition $u|_{t=T} = \varphi$. They also demonstrated that this reflected BSDE is a powerful tool to deal with contingent claims of American types in a financial market with constraints.

BSDE reflected within two barriers, a lower one L and an upper one U, was first investigated by Cvitanic and Karatzas (1996) where a type of nonlinear Dynkin games was formulated for a two-player model with zero-sum utility and each player chooses his own optimal exit time.

Stochastic optimal switching problems can be also solved by new types of oblique-reflected BSDEs.

A more general case of constrained BSDE is to find the smallest g-supersolution (Y, Z, K) with constraint $(Y_t, Z_t) \in \Gamma_t$ where, for each $t \in$ $[0, T]$, Γ_t (El Karoui and Quenez 1995; Cvitanic and Karatzas 1993; El Karoui et al. 1997a) for the problem of superhedging in a market with convex constrained portfolios (Cvitanic et al. 1998). The case with an arbitrary closed constraint was proved in Peng (1999).

Backward Stochastic Semigroup and g-Expectations

Let $\mathcal{E}_{t,T}^g[\xi] = Y_t$ where Y is the solution of BSDE (1). $(\mathcal{E}_{t,T}^g[\cdot])_{0 \leq t \leq T < \infty}$ has the (backward) semigroup property (Peng 1997)

$$\mathcal{E}_{s,t}^g[\mathcal{E}_{t,T}^g[\xi]] = \mathcal{E}_{s,T}^g[\xi], \quad \mathcal{E}_{T,T}^g[\xi]$$
$$= \xi, \quad 0 \leq s \leq t \leq T.$$

For a real valued BSDE, by the comparison theorem, the semigroup is monotone: $\mathcal{E}_{t,T}^g[\xi] \geq \mathcal{E}_{t,T}^g[\bar{\xi}]$, if $\xi \geq \bar{\xi}$. If moreover $g|_{z=0} = 0$, then the semigroup is constant preserving: $\mathcal{E}_{t,T}^g[c] \equiv c$. Thus the semigroup forms in fact a nonlinear expectation called g-expectation (since this nonlinear expectation is totally determined by the generator g).

This notion allows us to establish a nonlinear g-martingale theory, e.g., g-supermartingale decomposition theorem. Peng (1999) claims that, if Y is a square-integrable càdlàg g-supermartingale, then it has the unique decomposition: there exists a unique predictable, increasing, and càdlàg process A such that Y solves

$$-dY_t = g(t, Y_t, Z_t)dt + dA_t - Z_t dB_t.$$

A theoretically challenging and practically important problem is as follows: given an abstract family of expectations $(\mathcal{E}_{s,t}[\cdot])_{s \leq t}$ satisfying the same backward semigroup properties as these of g-expectation, can we find a function g such that $\mathcal{E}_{s,t} \equiv \mathcal{E}_{s,t}^g$? Coquet, Hu et al. (2005) proved that if $\mathcal{E}$ is dominated by g_μ-expectation with $g_\mu(z) = \mu|z|$ for a large enough constant $\mu > 0$, then there exists a unique function $g = g(t, \omega, z)$ satisfying μ-Lipschitz condition such that $(\mathcal{E}_{s,t}[\cdot])_{s \leq t}$ is in fact a g-expectation. For a concave dynamic expectation with an assumption much weaker than

the above domination condition, we can still find a function $g = g(t, z)$ with possibly singular values (Delbaen et al. 2010). For the case without the assumption of constant preservation, see Peng (2005). In practice, the above criterion is very useful to test whether a dynamic pricing mechanism of contingent contracts can be represented through a concrete function g.

A serious challenging problem in the stochastic control theory is as follows: it is based on a given probability space $(\Omega, \mathcal{F}, P)$. But in most practical situations, it is far from being true. In many risky situations, it is necessary to consider the uncertainty of the probability measures themselves, e.g., $\{P_\theta\}_{\theta \in \Theta}$, namely, the well-known Knightian uncertainty (Knight 1921). A new framework of G-expectation space $(\Omega, \mathcal{H}, \hat{\mathbb{E}})$ and the corresponding random and stochastic analysis (Itô's analysis) is introduced (see Peng 2007, 2010 and Soner et al. 2012) to replace the probability framework $(\Omega, \mathcal{F}, P)$. g-expectation is a special and typical case in this new theory.

Abstract

Basic principles for the development of computational methods for the analysis and design of linear time-invariant systems are discussed. These have been used in the design of the subroutine library SLICOT. The principles are illustrated on the basis of a method to check the controllability of a linear system.

Keywords

Accuracy; Basic numerical methods; Benchmarking; Controllability; Documentation and implementation standards; Efficiency; Software design

Introduction

Basic numerical methods for the analysis and design of dynamical systems are at the heart of most techniques in systems and control theory that are used to describe, control, or optimize industrial and economical processes. There are many methods available for all the different tasks in systems and control, but even though most of these methods are based on sound theoretical principles, many of them still fail when applied to real-life problems. The reasons for this may be quite diverse, such as the fact that the system dimensions are very large, that the underlying problem is very sensitive to small changes in the data, or that the method lacks numerical

robustness when implemented in a finite precision environment.

To overcome such failures, major efforts have been made in the last few decades to develop robust, well-implemented, and standardized software packages for computer-aided control systems design (Grübel 1983; Nag Slicot 1990; Wieslander 1977). Following the standards of modern software design, such packages should consist of numerically robust routines with known performance in terms of reliability and efficiency that can be used to form the basis of more complex control methods. Also to avoid duplication and to achieve efficiency and portability to different computational environments, it is essential to make maximal use of the established standard packages that are available for numerical computations, e.g., the **B**asic **L**inear **A**lgebra **S**ubroutines (BLAS) (Dongarra et al. 1990) or the **L**inear **A**lgebra **Pack**ages (LAPACK) (Anderson et al. 1992). On the basis of such standard packages, the next layer of more complex control methods can then be built in a robust way.

In the late 1980s, a working group was created in Europe to coordinate efforts and integrate and extend the earlier software developments in systems and control. Thanks to the support of the European Union, this eventually led to the development of the **S**ubroutine **L**ibrary **in** **Co**ntrol **T**heory (SLICOT) (Benner et al. 1999; SLICOT 2012). This library contains most of the basic computational methods for control systems design of linear time-invariant control systems.

An important feature of this and similar kind of subroutine libraries is that the development of further higher level methods is not restricted by specific requirements of the languages or data structures used and that the routines can be easily incorporated within other more user-friendly software systems (Gomez et al. 1997; MATLAB 2013). Usually, this *low-level reusability* can only be achieved by using a general-purpose programming language like C or Fortran.

We cannot present all the features of the SLICOT library here. Instead, we discuss its general philosophy in section "The Control Subroutine Library SLICOT" and illustrate these concepts in section "An Illustration" using one specific task, namely, checking the controllability of a system. We refer to SLICOT (2012) for more details on SLICOT and to Varga (2004) for a general discussion on numerical software for systems and control.

The Control Subroutine Library SLICOT

When designing a subroutine library of basic algorithms, one should make sure that it satisfies certain basic requirements and that it follows a strict standardization in implementation and documentation. It should also contain standardized test sets that can be used for benchmarking, and it should provide means for maintenance and portability to new computing environments. The subroutine library SLICOT was designed to satisfy the following basic recommendations that are typically expected in this context (Benner et al. 1999).

Robustness: A subroutine must either return reliable results or it must return an error or warning indicator, if the problem has not been well posed or if the problem does not fall in the class to which the algorithm is applicable or if the problem is too ill-conditioned to be solved in a particular computing environment.

Numerical stability and accuracy: Subroutines are supposed to return results that are as good as can be expected when working at a given precision. They also should provide an option to return a parameter estimating the accuracy actually achieved.

Efficiency: An algorithm should never be chosen for its speed if it fails to meet the usual standards of robustness, numerical stability, and accuracy, as described above. Efficiency must be evaluated, e.g., in terms of the number of floating-point operations, the memory requirements, or the number and cost of iterations to be performed.

Modern computer architectures: The requirements of modern computer architectures must be taken into account, such as shared

or distributed memory parallel processors, which are the standard environments of today. The differences in the various architectures may imply different choices of algorithms.

Comprehensive functional coverage: The routines of the library should solve control systems relevant computational problems and try to cover a comprehensive set of routines to make it functional for a wide range of users. The SLICOT library covers most of the numerical linear algebra methods needed in systems analysis and synthesis problems for standard and generalized state space models, such as Lyapunov, Sylvester, and Riccati equation solvers, transfer matrix factorizations, similarity and equivalence transformations, structure exploiting algorithms, and condition number estimators.

The implementation of subroutines for a library should be highly standardized, and it should be accompanied by a well-written online documentation as well as a user manual (see, e.g., standard Denham and Benson 1981; Working Group Software 1996) which is compatible with that of the LAPACK library (Anderson et al. 1992). Although such highly restricted standards often put a heavy burden on the programmer, it has been observed that it has a high importance for the reusability of software and it also has turned out to be a very valuable tool in teaching students how to implement algorithms in the context of their studies.

Benchmarking

In the validation of numerical software, it is extremely important to be able to test the correctness of the implementation as well as the performance of the method, which is one of the major steps in the construction of a software library. To achieve this, one needs a standardized set of benchmark examples that allows an evaluation of a method with respect to correctness, accuracy, and efficiency and to analyze the behavior of the method in extreme situations, i.e., on problems where the limit of the possible accuracy is reached. In the context of basic systems and control methods, several such benchmark collections have been developed (see, e.g., Benner et al. 1997; Frederick 1998, or http://www.slicot.org/index.php?site=benchmarks).

Maintenance, Open Access, and Archives

It is a major challenge to maintain a well-developed library accessible and usable over time when computer architectures and operating systems are changing rapidly, while keeping the library open for access to the user community. This usually requires financial resources that either have to be provided by public funding or by licensing the commercial use.

In the SLICOT library, this challenge has been addressed by the formation of the Niconet Association (http://www.niconet-ev.info/en/) which provides the current versions of the codes and all the documentations. Those of Release 4.5 are available under the GNU General Public License or from the archives of http://www.slicot.org/.

An Illustration

To give an illustration for the development of a basic control system routine, we consider the specific problem of checking controllability of a linear time-invariant control system. A linear time-invariant control problem has the form

$$\frac{dx}{dt} = Ax + Bu, \ t \in [t_0, \infty) \qquad (1)$$

Here x denotes the *state* and u the *input function*, and the system matrices are typically of the form $A \in \mathbb{R}^{n,n}, \ B \in \mathbb{R}^{n,m}$.

One of the most important topics in control is the question whether by an appropriate choice of input function $u(t)$ we can control the system from an arbitrary state to the null state. This property, called *controllability*, can be characterized by one of the following equivalent conditions (see Paige 1981).

Theorem 1 *The following are equivalent:*

(i) System (1) is controllable.

(ii) Rank $[B, AB, A^2B, \cdots, A^{n-1}B] = n$.

(iii) Rank $[B, A - \lambda I] = n \quad \forall \lambda \in \mathbb{C}$.

(iv) $\exists F$ *such that* A *and* $A + BF$ *have no common eigenvalues.*

The conditions of Theorem 1 are nice for theoretical purposes, but none of them is really adequate for the implementation of an algorithm that satisfies the requirements described in the previous section. Condition (ii) creates difficulties because the controllability matrix $K = [B, AB, A^2B, \cdots, A^{n-1}B]$ will be highly corrupted by roundoff errors. Condition (iii) can simply not be checked in finite time. However, it is sufficient to check this condition only for the eigenvalues of A, but this is extremely expensive. And finally, condition (iv) will almost always give disjoint spectra between A and $A + BF$ since the computation of eigenvalues is sensitive to roundoff.

To devise numerical procedures, one often resorts to the computation of canonical or condensed forms of the underlying system. To obtain such a form one employs controllability preserving linear transformations $x \mapsto Px$, $u \mapsto Qu$ with nonsingular matrices $P \in \mathbb{R}^{n,n}$, $Q \in \mathbb{R}^{m,m}$. The canonical form under these transformations is the Luenberger form (see Luenberger 1967). This form allows to check the controllability using the above criterion (iii) by simple inspection of the condensed matrices. This is ideal from a theoretical point of view but is very sensitive to small perturbations in the data, in particular because the transformation matrices may have arbitrary large norm, which may lead to large errors.

For the implementation as robust numerical software one uses instead transformations with real orthogonal matrices P, Q that can be implemented in a backward stable manner, i.e., the resulting backward error is bounded by a small constant times the unit roundoff **u** of the finite precision arithmetic, and employs for reliable rank determinations the well-known singular value decomposition (SVD) (see, e.g., Golub and Van Loan 1996).

Theorem 2 (Singular value decomposition) *Given* $A \in \mathbb{R}^{n,m}$, *then there exist orthogonal matrices* U, V *with* $U \in \mathbb{R}^{n,n}$, $V \in \mathbb{R}^{m,m}$, *such that* $A = U\Sigma V^T$ *and* $\Sigma \in \mathbb{R}^{n,m}$ *is quasi-diagonal, i.e.,*

$$\Sigma = \begin{bmatrix} \Sigma_r & 0 \\ 0 & 0 \end{bmatrix} \text{ where } \Sigma_r = \begin{bmatrix} \sigma_1 & & \\ & \ddots & \\ & & \sigma_r \end{bmatrix},$$

and the nonzero singular values σ_i *are ordered as* $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$.

The SVD presents the *best* way to determine (numerical) ranks of matrices in finite precision arithmetic by counting the number of singular values satisfying $\sigma_j \geq \mathbf{u}\sigma_1$ and by putting those for which $\sigma_j < \mathbf{u}\sigma_1$ equal to zero. The computational method for the SVD is well established and analyzed, and it has been implemented in the LAPACK routine SGESVD (see http://www.netlib.org/lapack/). A faster but less reliable alternative to compute the numerical rank of a matrix A is its QR factorization with pivoting (see, e.g., Golub and Van Loan 1996).

Theorem 3 (QRE decomposition) *Given* $A \in \mathbb{R}^{n,m}$, *then there exists an orthogonal matrix* $Q \in \mathbb{R}^{n,n}$ *and a permutation* $E \in \mathbb{R}^{m,m}$, *such that* $A = QRE^T$ *and* $R \in \mathbb{R}^{n,m}$ *is trapezoidal, i.e.,*

$$R = \begin{bmatrix} r_{11} & \dots & r_{1l} & \dots & r_{1m} \\ & \ddots & & & \vdots \\ & & r_{ll} & \dots & r_{lm} \\ 0 & & & 0 & \end{bmatrix}.$$

and the nonzero diagonal entries r_{ii} *are ordered as* $r_{11} \geq \cdots \geq r_{ll} > 0$.

The (numerical) rank in this case is again obtained by counting the diagonal elements $r_{ii} \geq \mathbf{u}r_{11}$.

One can use such orthogonal transformations to construct the controllability staircase form (see Van Dooren 1981).

Theorem 4 (Staircase form) *Given matrices* $A \in R^{n,n}$, $B \in R^{n,m}$, *then there exist orthogonal matrices* P, Q *with* $P \in \mathbb{R}^{n,n}$, $Q \in \mathbb{R}^{m,m}$, *so that*

$$PAP^T = \begin{bmatrix} A_{11} & \cdots & & \cdots & A_{1,r-1} & A_{1,r} \\ A_{21} & \ddots & & & \vdots & \vdots \\ & \ddots & \ddots & & \vdots & \vdots \\ & & A_{r-1,r-2} & A_{r-1,r-1} & A_{r-1,r} \\ 0 & \cdots & 0 & 0 & A_{rr} \end{bmatrix} \begin{matrix} n_1 \\ n_2 \\ \vdots \\ n_{r-1} \\ n_r \end{matrix}$$
$$ \begin{matrix} n_1 & \cdots & n_{r-2} & n_{r-1} & n_r \end{matrix}$$

$$PBQ = \begin{bmatrix} B_1 & 0 \\ 0 & 0 \\ \vdots & \vdots \\ \vdots & \vdots \\ \vdots & \vdots \\ 0 & 0 \end{bmatrix} \begin{matrix} n_1 \\ n_2 \\ \vdots \\ \vdots \\ \vdots \\ n_r \end{matrix} \qquad (2)$$
$$ \begin{matrix} n_1 & m - n_1 \end{matrix}$$

where $n_1 \geq n_2 \geq \cdots \geq n_{r-1} \geq n_r \geq 0, n_{r-1} > 0$, $A_{i,i-1} = \begin{bmatrix} \Sigma_{i,i-1} & 0 \end{bmatrix}$, with nonsingular blocks $\Sigma_{i,i-1} \in \mathbb{R}^{n_i,n_i}$ and $B_1 \in \mathbb{R}^{n_1,n_1}$.

Notice that when using the reduced pair in condition (iii) of Theorem 1, the controllability condition is just $n_r = 0$, which is simply checked by inspection. A numerically stable algorithm to compute the staircase form of Theorem 4 is given below. It is based on the use of the singular value decomposition, but one could also have used instead the QR decomposition with column pivoting.

Staircase Algorithm
Input: $A \in \mathbb{R}^{n,n}, B \in \mathbb{R}^{n,m}$
Output: PAP^T, PBQ in the form (2), P, Q orthogonal

Step 0: Perform an SVD $B = U_B \begin{bmatrix} \Sigma_B & 0 \\ 0 & 0 \end{bmatrix} V_B^T$ with nonsingular and diagonal $\Sigma_B \in \mathbb{R}^{n_1,n_1}$. Set $P := U_B^T, Q := V_B$, so that

$$A := U_B^T A U_B = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

$$B := U_B^T B V_B = \begin{bmatrix} \Sigma_B & 0 \\ 0 & 0 \end{bmatrix}$$

with A_{11} of size $n_1 \times n_1$.

Step 1: Perform an SVD $A_{21} = U_{21} \begin{bmatrix} \Sigma_{21} & 0 \\ 0 & 0 \end{bmatrix} V_{21}^T$ with nonsingular and diagonal $\Sigma_{21} \in \mathbb{R}^{n_2,n_2}$. Set

$$P_2 := \begin{bmatrix} V_{21}^T & 0 \\ 0 & U_{21}^T \end{bmatrix}, \quad P := P_2 P$$

so that

$$A := P_2 A P_2^T =: \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{bmatrix},$$

$$B := P_2 B =: \begin{bmatrix} B_1 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix},$$

where $A_{21} = \begin{bmatrix} \Sigma_{21} & 0 \end{bmatrix}$, and $B_1 := V_{21}^T \Sigma_B$.

Step 2:
i = 3
DO WHILE ($n_{i-1} > 0$ AND $A_{i,i-1} \neq 0$).
 Perform an SVD of $A_{i,i-1} = U_{i,i-1} \begin{bmatrix} \Sigma_{i,i-1} & 0 \\ 0 & 0 \end{bmatrix} V_{i,i-1}^T$ with
 $\Sigma_{i,i-1} \in \mathbb{R}^{n_i,n_i}$ nonsingular and diagonal.
 Set

$$P_i := \begin{bmatrix} I_{n_1} \\ & \ddots \\ & & I_{n_{i-2}} \\ & & & V_{i,i-1}^T \\ & & & & U_{i,i-1}^T \end{bmatrix}, P := P_i P,$$

so that

$$A := P_i A P_i^T =: \begin{bmatrix} A_{11} & \cdots & & & A_{1,i+1} \\ A_{21} & \ddots & & & A_{2,i+1} \\ & \ddots & \ddots & & \vdots \\ & & A_{i,i-1} & A_{i,i} & \vdots \\ 0 & & & A_{i+1,i} & A_{i+1,i+1} \end{bmatrix}$$

where $A_{i,i-1} = \begin{bmatrix} \Sigma_{i,i-1} & 0 \end{bmatrix}$.
$i := i + 1$
END
$r := i$

It is clear that this algorithm will stop with $n_i = 0$ or $A_{i,i-1} = 0$. In every step, the remaining block shrinks at least by 1 row/column, as long as Rank $A_{i,i-1} > 1$, so that the algorithm stops after maximally $n - 1$ steps. It has been shown in Van Dooren (1981) that system (1) is controllable if and only if in the staircase form of (A, B) one has $n_r = 0$.

It should be noted that the updating transformations P_i of this algorithm will affect previously created "stairs" so that the blocks denoted as $\Sigma_{i,i-1}$ will not be diagonal anymore, but their singular values are unchanged. This is critical in the decision about the controllability of the pair (A, B) since it depends on the numerical rank of the submatrices $A_{i,i-1}$ and B (see Demmel and Kågström 1993). Based on this and a detailed error and perturbation analysis, the Staircase Algorithm has been implemented in the SLICOT routine `AB01OD`, and it uses in the worst-case $\mathcal{O}(n^4)$ flops (a "flop" is an elementary floating-point operation $+, -, *,$ or $/$). For efficiency reasons, the SLICOT routine `AB01OD` does not use SVDs for rank decisions, but QR decompositions with column pivoting. When applying the corresponding orthogonal transformations to the system without accumulating them, the complexity can be reduced to $\mathcal{O}(n^3)$ flops. It has been provided with error bounds, condition estimates, and warning strategies.

Summary and Future Directions

We have presented the SLICOT library and the basic principles for the design of such basic subroutine libraries. To illustrate these principles, we have presented the development of a method for checking controllability for a linear time-invariant control system. But the SLICOT library contains much more than that. It essentially covers most of the problems listed in the selected reprint volume (Patel et al. 1994). This volume contained in 1994 the state of the art in numerical methods for systems and control, but the field has strongly evolved since then. Examples of areas that were not in this volume but that are included in SLICOT are periodic systems, differential algebraic equations, and model reduction. Areas which still need new results and software are the control of large-scale systems, obtained either from discretizations of partial differential equations or from the interconnection of a large number of interacting systems. But it is unclear for the moment which will be the methods of choice for such problems. We still need to understand the numerical challenges in such areas, before we can propose numerically reliable software for these problems: the area is still quite open for new developments.

Bilinear Control of Schrödinger PDEs

Karine Beauchard[1] and Pierre Rouchon[2]
[1]CNRS, CMLS, Ecole Polytechnique, Palaiseau, France
[2]Centre Automatique et Systèmes, Mines ParisTech, Paris Cedex 06, France

Abstract

This entry is an introduction to modern issues about controllability of Schrödinger PDEs with bilinear controls. This model is pertinent for a quantum particle, controlled by an electric field. We review recent developments in the field, with discrimination between exact and approximate controllabilities, in finite or infinite time. We also underline the variety of mathematical tools used by various teams in the last decade. The results are illustrated on several classical examples.

Keywords

Introduction

A quantum particle, in a space with dimension N ($N = 1, 2, 3$), in a potential $V = V(x)$, and in an electric field $u = u(t)$, is represented by a wave function $\psi : (t, x) \in \mathbb{R} \times \Omega \to \mathbb{C}$ on the $L^2(\Omega, \mathbb{C})$ sphere $\mathcal{S}$

$$\int_\Omega |\psi(t, x)|^2 \, dx = 1, \quad \forall t \in \mathbb{R},$$

where $\Omega \subset \mathbb{R}^N$ is a possibly unbounded open domain. In first approximation, the time evolution of the wave function is given by the Schrödinger equation,

$$\begin{cases} i \, \partial_t \psi(t, x) = (-\Delta + V) \, \psi(t, x) \\ -u(t)\mu(x) \, \psi(t, x), \ t \in (0, +\infty), x \in \Omega, \\ \psi(t, x) = 0, \ x \in \partial\Omega \end{cases} \tag{1}$$

where μ is the dipolar moment of the particle and $\hbar = 1$ here. Sometimes, this equation is considered in the more abstract framework

$$i \frac{d}{dt} \psi = (H_0 + u(t) H_1) \, \psi \tag{2}$$

where ψ lives on the unit sphere of a separable Hilbert space $\mathcal{H}$ and the Hamiltonians H_0, H_1 are Hermitian operators on $\mathcal{H}$. A natural question, with many practical applications, is the existence of a control u that steers the wave function ψ from a given initial state ψ_0, to a prescribed target ψ_f.

The goal of this survey is to present well-established results concerning exact and approximate controllabilities for the bilinear control system (1), with applications to relevant examples. The main difficulties are the infinite

dimension of $\mathcal{H}$ and the nonlinearity of the control system.

Preliminary Results

When the Hilbert space $\mathcal{H}$ has finite dimension n, then controllability of Eq. (2) is well understood (D'Alessandro 2008). If, for example, the Lie algebra spanned by H_0 and H_1 coincides with $u(n)$, the set of skew-Hermitian matrices, then system (2) is globally controllable: for any initial and final states $\psi_0, \psi_f \in \mathcal{H}$ of length one, there exist $T > 0$ and a bounded open-loop control $[0, T] \ni t \mapsto u(t)$ steering ψ from $\psi(0) = \psi_0$ to $\psi(T) = \psi_f$.

In infinite dimension, this idea served to intuit a negative controllability result in Mirrahimi and Rouchon (2004), but the above characterization cannot be generalized because iterated Lie brackets of unbounded operators are not necessarily well defined. For example, the quantum harmonic oscillator

$$i \, \partial_t \psi \, (t, x) = - \, \partial_x^2 \psi \, (t, x) + x^2 \psi \, (t, x)$$
$$- u \, (t) \, x \psi \, (t, x) \, , \quad x \in \mathbb{R}, \quad (3)$$

is not controllable (in any reasonable sense) (Mirrahimi and Rouchon 2004) even if all its Galerkin approximations are controllable (Fu et al. 2001). Thus, much care is required in the use of Galerkin approximations to prove controllability in infinite dimension. This motivates the search of different methods to study exact controllability of bilinear PDEs of form (1).

In infinite dimension, the norms need to be specified. In this article, we use Sobolev norms. For $s \in \mathbb{N}$, the Sobolev space $H^s(\Omega)$ is the space of functions $\psi : \Omega \to \mathbb{C}$ with square integrable derivatives $d^k \psi$ for $k = 0, \ldots, s$ (derivatives are well defined in the distribution sense). $H^s(\Omega)$ is endowed with the norm $\| \psi \|_{H^s} := \left(\sum_{k=0}^s \| d^k \psi \|_{L^2(\Omega)}^2 \right)^{1/2}$. We also use the space $H_0^1(\Omega)$ which contains functions $\psi \in H^1(\Omega)$ that vanish on the boundary $\partial \Omega$ (in the trace sense) (Brézis 1999).

The first control result of the literature states the noncontrollability of system (1) in $(H^2 \cap H_0^1)$ $(\Omega) \cap \mathcal{S}$ with controls $u \in L^2((0, T), \mathbb{R})$ (Ball et al. 1982; Turinici 2000). More precisely, by applying $L^2(0, T)$ controls u, the reachable wave functions $\psi(T)$ form a subset of $(H^2 \cap H_0^1)$ $(\Omega) \cap \mathcal{S}$ with empty interior. This statement does not give obstructions for system (1) to be controllable in different functional spaces as we will see below, but it indicates that controllability issues are much more subtle in infinite dimension than in finite dimension.

Local Exact Controllability

In 1D and with Discrete Spectrum
This section is devoted to the 1D PDE:

$$\begin{cases} i \, \partial_t \psi \, (t, x) = - \partial_x^2 \psi \, (t, x) \\ - u(t) \mu \, (x) \, \psi \, (t, x) \, , \quad x \in (0, 1) \, , t \in (0, T) \, , \\ \psi \, (t, 0) = \psi \, (t, 1) = 0. \end{cases}$$
$$(4)$$

We call "ground state" the solution of the free system ($u = 0$) built with the first eigenvalue and eigenvector of $-\partial_x^2$: $\psi_1(t, x) = \sqrt{2} \, \sin(\pi x) \, e^{-i \pi^2 t}$. Under appropriate assumptions on the dipolar moment μ, then system (4) is controllable around the ground state, locally in $H_{(0)}^3 \, (0, 1) \cap \mathcal{S}$, with controls in $L^2((0, T), \mathbb{R})$, as stated below.

Theorem 1 *Assume $\mu \in H^3((0, 1), \mathbb{R})$ and*

$$\left| \int_0^1 \mu \, (x) \sin \, (\pi x) \sin \, (k \pi x) \, dx \right| \geq \frac{c}{k^3}, \, \forall k \in \mathbb{N}^*$$
$$(5)$$

for some constant $c > 0$. Then, for every $T > 0$, there exists $\delta > 0$ such that for every $\psi_0, \psi_f \in \mathcal{S} \cap H_{(0)}^3 \, ((0, 1), \mathbb{C})$ with $\| \psi_0 - \psi_1(0) \|_{H^3} + \| \psi_f - \psi_1(T) \|_{H^3} < \delta$, there exists $u \in L^2((0, T), \mathbb{R})$ such that the solution of (4) with initial condition $\psi(0, x) = \psi_0(x)$ satisfies $\psi(T) = \psi_f$.

Here, $H_{(0)}^3 \, (0, 1) := \{ \psi \in H^3((0, 1), \mathbb{C}); \psi = \psi'' = 0 \text{ at } x = 0, 1 \}$. We refer to Beauchard

and Laurent (2010) and Beauchard et al. (2013) for proof and generalizations to nonlinear PDEs. The proof relies on the linearization principle, by applying the classical inverse mapping theorem to the endpoint map. Controllability of the linearized system around the ground state is a consequence of assumption (5) and classical results about trigonometric moment problems. A subtle smoothing effect allows to prove C^1 regularity of the endpoint map.

The assumption (5) holds for generic $\mu \in H^3((0,1), \mathbb{R})$ and plays a key role for local exact controllability to hold in *small* time T. In Beauchard and Morancey (2014), local exact controllability is proved under the weaker assumption, namely, $\mu'(0) \pm \mu'(1) \neq 0$, but only in *large* time T.

Moreover, under appropriate assumptions on μ, references Coron (2006) and Beauchard and Morancey (2014) propose explicit motions that are impossible in small time T, with small controls in L^2. Thus, a positive minimal time is required for local exact controllability, even if information propagates at infinite speed. This minimal time is due to nonlinearities; its characterization is an open problem.

Actually, assumption $\mu'(0) \pm \mu'(1) \neq 0$ is not necessary for local exact controllability in large time. For instance, the quantum box, i.e.,

$$\begin{cases} i\,\partial_t \psi\,(t,x) = -\partial_x^2 \psi\,(t,x) \\ -u(t)x\psi\,(t,x)\,, \quad x \in (0,1)\,, \\ \psi\,(t,0) = \psi\,(t,1) = 0, \end{cases} \quad (6)$$

is treated in Beauchard (2005). Of course, these results are proved with additional techniques: power series expansions and Coron's return method (Coron 2007).

There is no contradiction between the negative result of section "Preliminary Results" and the positive result of Theorem 1. Indeed, the wave function cannot be steered between any two points ψ_0, ψ_f of $H^2 \cap H_0^1$, but it can be steered between any two points ψ_0, ψ_f of $H_{(0)}^3$, which is smaller than $H^2 \cap H_0^1$. In particular, $H_{(0)}^3\,((0,1), \mathbb{C})$ has an empty interior in $H_{(0)}^2\,((0,1), \mathbb{C})$. Thus, there is no incompatibility between the reachable set to have empty interior

in $H^2 \cap H_0^1$ and the reachable set to coincide with $H_{(0)}^3$.

Open Problems in Multi-D or with Continuous Spectrum

The linearization principle used to prove Theorem 1 does not work in multi-D: the trigonometric moment problem, associated to the controllability of the linearized system, cannot be solved. Indeed, its frequencies, which are the eigenvalues of the Dirichlet Laplacian operator, do not satisfy a required gap condition (Loreti and Komornik 2005).

The study of a toy model (Beauchard 2011) suggests that if local controllability holds in 2D (with a priori bounded L^2-controls) then a positive minimal time is required, whatever μ is. The appropriate functional frame for such a result is an open problem.

In 3D or in the presence of continuous spectrum, we conjecture that local exact controllability does not hold (with a priori bounded L^2-controls) because the gap condition in the spectrum of the Dirichlet Laplacian operator is violated (see Beauchard et al. (2010) for a toy model from nuclear magnetic resonance and ensemble controllability as originally stated in Li and Khaneja (2009)). Thus, exact controllability should be investigated with controls that are not a priori bounded in L^2; this requires new techniques. We refer to Nersesyan and Nersisyan (2012a) for precise negative results.

Finally, we emphasize that exact controllability in multi-D but in *infinite* time has been proved in Nersesyan and Nersisyan (2012a,b), with techniques similar to one used in the proof of Theorem 1.

Approximate Controllability

Different approaches have been developed to prove approximate controllability.

Lyapunov Techniques
Due to measurement effect and back action, closed-loop controls in the Schrödinger frame are

not appropriate. However, closed-loop controls may be computed via numerical simulations and then applied to real quantum systems in open loop, without measurement. Then, the strategy consists in designing damping feedback laws, thanks to a controlled Lyapunov function, which encodes the distance to the target. In finite dimension, the convergence proof relies on LaSalle invariance principle. In infinite dimension, this principle works when the trajectories of the closed-loop system are compact (in the appropriate space), which is often difficult to prove. Thus, two adaptations have been proposed: approximate convergence (Beauchard and Mirrahimi 2009; Mirrahimi 2009) and weak convergence (Beauchard and Nersesyan 2010) to the target.

Variational Methods and Global Exact Controllability

The global approximate controllability of (1), in any Sobolev space, is proved in Nersesvan (2010), under generic assumptions on (V, μ), with Lyapunov techniques and variational arguments.

Theorem 2 *Let $V, \mu \in C^\infty(\overline{\Omega}, \mathbb{R})$ and $(\lambda_j)_{j \in N*}, (\phi_j)_{j \in N*}$ be the eigenvalues and normalized eigenvectors of $(-\Delta + V)$. Assume $\langle \mu \phi_j, \phi_1 \rangle \neq 0$, for all $j \geq 2$ and $\lambda_1 - \lambda_j \neq \lambda_p - \lambda_q$ for all $j, p, q \in \mathbb{N}*$ such that $\{1, j\} \neq \{p, q\}; j \neq 1$. Then, for every $s > 0$, the system (1) is globally approximately controllable in $H^s_{(V)}: D\left[(-\Delta + V)^{s/2}\right]$, the domain of $(-\Delta + V)^{s/2}$: for every $\epsilon, \delta > 0$ and $\psi_0 \in \mathcal{S} \cap H^s_{(V)}$, there exist a time $T > 0$ and a control $u \in C_0^\infty((0, T), \mathbb{R})$ such that the solution of (1) with initial condition $\psi(0) = \psi_0$ satisfies $\|\psi(T) - \phi_1\|_{H^{s-\delta}_{(V)}} < \epsilon$.*

This theorem is of particular importance. Indeed, in 1D and for appropriate choices of (V, μ), *global* exact controllability of (1) in H^{3+} can be proved by combining the following:

- Global approximate controllability in H^3 given by Theorem 2,
- Local exact controllability in H^3 given by Theorem 1,

- Time reversibility of the Schrödinger equation (i.e., if $(\psi(t, x), u(t))$ is a trajectory, then so is $(\psi^*(T - t, x), u(T - t))$ where ψ^* is the complex conjugate of ψ).

Let us expose this strategy on the quantum box (6). First, one can check the assumptions of Theorem 2 with $V(x) = \gamma x$ and $\mu(x) = (1-\gamma)x$ when $\gamma > 0$ is small enough. This means that, in (6), we consider controls $u(t)$ of the form $\gamma + u(t)$. Thus, an initial condition $\psi_0 \in H^{3+}_{(0)}$ can be steered arbitrarily close to the first eigenvector $\varphi_{1,\gamma}$ of $(-\partial_x^2 + \gamma x)$, in H^3 norm. Moreover, by a variant of Theorem 1, the local exact controllability of (6) holds in $H^3_{(0)}$ around $\phi_{1,\gamma}$. Therefore, the initial condition $\psi_0 \in H^{3+}_{(0)}$ can be steered exactly to $\phi_{1,\gamma}$ in finite time. By the time reversibility of the Schrödinger equation, we can also steer exactly the solution from $\phi_{1,\gamma}$ to any target $\psi_f \in H^{3+}$. Therefore, the solution can be steered exactly from any initial condition $\psi_0 \in H^{3+}_{(0)}$ to any target $\psi_f \in H^{3+}_{(0)}$ in finite time.

Geometric Techniques Applied to Galerkin Approximations

In Boscain et al. (2012, 2013) and Chambrion et al. (2009) the authors study the control of Schrödinger PDEs, in the abstract form (2) and under technical assumptions on the (unbounded) operators H_0 and H_1 that ensure the existence of solutions with piecewise constant controls u:

1. H_0 is skew-adjoint on its domain $D(H_0)$.
2. There exists a Hilbert basis $(\varphi_k)_{k \in N}$ of $\mathcal{H}$ made of eigenvectors of $H_0: H_0 \phi_k = i\lambda_k \phi_k$ and $\phi_k \in D(H_1), \forall k \in \mathbb{N}$.
3. $H_0 + uH_1$ is essentially skew-adjoint (not necessarily with domain $D(H_0)$) for every $u \in [0, \delta]$ for some $\delta > 0$.
4. $\langle H_1 \varphi_j, \varphi_k \rangle = 0$ for every $j, k \in \mathbb{N}$ such that $\lambda_j = \lambda_k$ and $j \neq k$.

Theorem 3 *Assume that, for every $j, k \in \mathbb{N}$, there exists a finite number of integers $p_1, \ldots, p_r \in \mathbb{N}$ such that*

$$p_1 = j, \ p_r = k, \ \langle H_1 \varphi_{p_l}, \varphi_{p_{l+1}} \rangle$$
$$\neq 0, \forall l = 1, \ldots, r - 1$$

$|\lambda_L - \lambda_M| \neq |\lambda_{p_l} - \lambda_{p_{l+1}}|, \forall 1 \leq l \leq r - 1$, $LM \in \mathbb{N}$ with $\{L, M\} \neq \{p_l, p_{l+1}\}$.

Then for every $\epsilon > 0$ and ψ_0, ψ_f in the unit sphere of $\mathcal{H}$, there exists a piecewise constant function $u : [0, T_\epsilon] \to [0, \delta]$ such that the solution of (2) with initial condition $\psi(0) = \psi_0$ satisfies $\|\psi(T_\epsilon) - \psi_f\|_{\mathcal{H}} < \epsilon$.

We refer to Boscain et al. (2012, 2013) and Chambrion et al. (2009) for proof and additional results such as estimates on the L^1 norm of the control. Note that H_0 is not necessarily of the form $(-\Delta + V)$, H_1 can be unbounded, δ may be arbitrary small, and the two assumptions are generic with respect to (H_0, H_1). The connectivity and transition frequency conditions in Theorem 3 mean physically that each pair of H_0 eigenstates is connected via a finite number of first-order (one-photon) transitions and that the transition frequencies between pairs of eigenstates are all different.

Note that, contrary to Theorems 2, Theorem 3 cannot be combined with Theorem 1 to prove global exact controllability. Indeed, functional spaces are different: $\mathcal{H} = L^2(\Omega)$ in Theorem 3, whereas H^3-regularity is required for Theorem 1.

This kind of results applies to several relevant examples such as the control of a particle in a quantum box by an electric field (6) and the control of the planar rotation of a linear molecule by means of two electric fields:

$$i \, \partial_t \psi(t, \theta) = \left(-\partial_0^2 + u_1(t) \cos(\theta) + u_2(t) \sin(\theta)\right) \psi(t, \theta), \quad \theta \in \mathbb{T}$$

where $\mathbb{T}$ is the lD-torus. However, several other systems of physical interest are not covered by these results such as trapped ions modeled by two coupled quantum harmonic oscillators. In Ervedoza and Puel (2009), specific methods have been used to prove their approximate controllability.

Concluding Remarks

The variety of methods developed by different authors to characterize controllability of Schrödinger PDEs with bilinear control is the sign of a rich structure and subtle nature of control issues. New methods will probably be necessary to answer the remaining open problems in the field.

This survey is far from being complete. In particular, we do not consider numerical methods to derive the steering control such as those used in NMR (Nielsen et al. 2010) to achieve robustness versus parameter uncertainties or such as monotone algorithms (Baudouin and Salomon 2008; Liao et al. 2011) for optimal control (Cancès et al. 2000). We do not consider also open quantum systems where the state is then the density operator ρ, a nonnegative Hermitian operator with unit trace on H. The Schrödinger equation is then replaced by the Lindblad equation:

$$\frac{d}{dt}\rho = -\iota \left[H_0 + uH_1, \rho\right] + \sum_\nu L_\nu \rho L_\nu^\dagger$$
$$-\frac{1}{2}\left(L_\nu^\dagger L_\nu \rho + \rho L_\nu^\dagger L_\nu\right)$$

with operator L_ν related to the decoherence channel ν. Even in the case of finite dimensional Hilbert space H, controllability of such system is not yet well understood and characterized (see Altafini (2003) and Kurniawan et al. (2012)).

Boundary Control of 1-D Hyperbolic Systems

Georges Bastin[1] and Jean-Michel Coron[2]
[1]Department of Mathematical Engineering, University Catholique de Louvain, Louvain-La-Neuve, Belgium
[2]Laboratoire Jacques-Louis Lions, University Pierre et Marie Curie, Paris, France

Abstract

One-dimensional hyperbolic systems are commonly used to describe the evolution of various physical systems. For many of these systems, controls are available on the boundary. There

are then two natural questions: controllability (steer the system from a given state to a desired target) and stabilization (construct feedback laws leading to a good behavior of the closed loop system around a given set point).

Keywords

Chromatography; Controllability; Electrical lines; Hyperbolic systems; Open channels; Road traffic; Stabilization

One-Dimensional Hyperbolic Systems

The operation of many physical systems may be represented by hyperbolic systems in one space dimension. These systems are described by the following partial differential equation:

$$Y_t + A(Y)Y_x = 0, \ \ t \in [0, T], \ \ x \in [0, L], \ (1)$$

where:
- t and x are two independent variables: a time variable $t \in [0, T]$ and a space variable $x \in [0, L]$ over a finite interval.
- $Y : [0, T] \times [0, L] \rightarrow \mathbb{R}^n$ is the vector of state variables.
- $A : \mathbb{R}^n \rightarrow \mathcal{M}_{n,n}(\mathbb{R})$ with $\mathcal{M}_{n,n}(\mathbb{R})$ is the set of $n \times n$ real matrices.
- Y_t and Y_x denote the partial derivatives of Y with respect to t and x, respectively.

The system (1) is **hyperbolic** which means that $A(Y)$ has n distinct real eigenvalues (called characteristic velocities) for all Y in a domain of $\mathbb{R}^n$. Here are some typical examples of physical models having the form of a hyperbolic system.

Electrical Lines

First proposed by Heaviside in (1885, 1886 and 1887), the equations of (lossless) electrical lines (also called telegrapher equations) describe the propagation of current and voltage along electrical transmission lines (see Fig. 1). It is a hyperbolic system of the following form:

$$\begin{pmatrix} I_t \\ V_t \end{pmatrix} + \begin{pmatrix} 0 & L_s^{-1} \\ C_s^{-1} & 0 \end{pmatrix} \begin{pmatrix} I_x \\ V_x \end{pmatrix} = 0, \quad (2)$$

where $I(t, x)$ is the current intensity, $V(t, x)$ is the voltage, L_s is the self-inductance per unit length, and C_s is the self-capacitance per unit length. The system has two characteristic velocities (which are the eigenvalues of the matrix A):

$$\lambda_1 = \frac{1}{\sqrt{L_s C_s}} > 0 > \lambda_2 = -\frac{1}{\sqrt{L_s C_s}}. \quad (3)$$

Saint-Venant Equation for Open Channels

First proposed by Barré de Saint-Venant in (1871), the Saint-Venant equations (also called *shallow water equations*) describe the propagation of water in open channels (see Fig. 2). In the case of a horizontal channel with rectangular cross section, unit width, and negligible friction, the Saint-Venant model is a hyperbolic system of the form

$$\begin{pmatrix} H_t \\ V_t \end{pmatrix} + \begin{pmatrix} V & H \\ g & V \end{pmatrix} \begin{pmatrix} H_x \\ V_x \end{pmatrix} = 0, \quad (4)$$

where $H(t, x)$ is the water depth, $V(t, x)$ is the water horizontal velocity, and g is the gravity acceleration. Under subcritical flow conditions, the system is hyperbolic with characteristic velocities

$$\lambda_1 = V + \sqrt{gH} > 0 > \lambda_2 = V - \sqrt{gH}. \quad (5)$$

### Aw-Rascle Equations for Fluid Models of Road Traffic

In the fluid paradigm for road traffic modeling, the traffic is described in terms of two basic macroscopic state variables: the density $\varrho(t, x)$ and the speed $V(t, x)$ of the vehicles at position x along the road at time t. The following dynamical model for road traffic was proposed by Aw and Rascle in (2000):

$$\begin{pmatrix} \varrho_t \\ V_t \end{pmatrix} + F(Y) \begin{pmatrix} V & \varrho \\ 0 & V - Q(\varrho) \end{pmatrix} \begin{pmatrix} \varrho_t \\ V_t \end{pmatrix} = 0. \quad (6)$$
Boundary Control of 1-D Hyperbolic Systems, Fig. 1 Transmission line connecting a power supply to a resistive load R_ℓ; the power supply is represented by a Thevenin equivalent with *efm* $U(t)$ and internal resistance R_g

Boundary Control of 1-D Hyperbolic Systems, Fig. 2 Lateral view of a pool of a horizontal open channel
The system is hyperbolic with characteristic velocities

$$\lambda_1 = V \; > \; \lambda_2 = V - Q(\varrho). \qquad (7)$$

In this model the first equation of (6) is a continuity equation that represents the conservation of the number of vehicles on the road. The second equation of (6) is a phenomenological model describing the speed variations induced by the driver's behavior.

Chromatography

In chromatography, a mixture of species with different affinities is injected in the carrying fluid at the entrance of the process as illustrated in Fig. 3. The various substances travel at different propagation speeds and are ultimately separated in different bands. The dynamics of the mixture are described by a system of partial differential equations:

$$(P_i + L_i(P))_t + V(P_i)_x = 0 \; \; i = 1, \ldots, n,$$

$$L_i(P) = \frac{k_i P_i}{1 + \sum_j k_j P_j / P_{\max}}, \qquad (8)$$
Boundary Control of 1-D Hyperbolic Systems, Fig. 3 Principle of chromatography

where P_i $(i = 1, \ldots, n)$ denote the densities of the n carried species. The function $L_i(P)$

(called the "Langmuir isotherm") was proposed by Langmuir in (1916).

Boundary Control

Boundary control of 1-D hyperbolic systems refers to situations where manipulated control inputs are physically located at the boundaries. Formally, this means that the system (1) is considered under n boundary conditions having the general form

$$B\big(Y(t,0), Y(t,L), U(t)\big) = 0, \qquad (9)$$

with $B : \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^q \rightarrow \mathbb{R}^n$. The dependence of the map B on $(Y(t,0), Y(t,L))$ refers to natural physical constraints on the system. The function $U(t) \in \mathbb{R}^q$ represents a set of q exogenous control inputs. The following examples illustrate how the control boundary conditions (9) may be defined for some commonly used control devices:

1. **Electrical lines.** For the circuit represented in Fig. 1, the line model (2) is to be considered under the following boundary conditions:

$$V(t,0) + R_g I(t,0) = U(t),$$
$$V(t,L) - R_\ell I(t,L) = 0.$$

   The telegrapher equations (2) coupled with these boundary conditions constitute therefore a boundary control system with the voltage $U(t)$ as control input.

2. **Open channels.** A standard situation is when the boundary conditions are assigned by tunable hydraulic gates as in irrigation canals and navigable rivers; see Fig. 4.

   The hydraulic model of mobile spillways gives the boundary conditions

$$H(t,0)V(t,0) = k_G \sqrt{\big[Z_0(t) - U_0(t)\big]^3},$$
$$H(t,L)V(t,L) = k_G \sqrt{\big[H(t,L) - U_L(t)\big]^3},$$

   where $H(t,0)$ and $H(t,L)$ denote the water depth at the boundaries inside the pool, $Z_0(t)$ and $Z_L(t)$ are the water levels on the other side of the gate, k_G is a constant gate shape parameter, and U_0 and U_L represent the weir elevations. The Saint-Venant equations coupled to these boundary conditions constitute a boundary control system with $U_0(t)$ and $U_L(t)$ as command signals.

3. **Ramp metering.** Ramp metering is a strategy that uses traffic lights to regulate the flow of traffic entering freeways according to measured traffic conditions as illustrated in Fig. 5. For the stretch of motorway represented in this figure, the boundary conditions are

$$\varrho(t,0)V(t,0) = Q_{\text{in}}(t) + U(t),$$
$$\varrho(t,L)V(t,L) = Q_{\text{out}}(t),$$

   where $U(t)$ is the inflow rate controlled by the traffic lights. The Aw-Rascle equations (6) coupled to these boundary conditions constitute a boundary control system with $U(t)$ as
Boundary Control of 1-D Hyperbolic Systems, Fig. 4 Hydraulic gates at the input and the output of a pool
Boundary Control of 1-D Hyperbolic Systems, Fig. 5 Ramp metering on a stretch of a motorway

the command signal. In a feedback implementation of the ramp metering strategy, $U(t)$ may be a function of the measured disturbances $Q_{\text{int}}(t)$ or $Q_{\text{out}}(t)$ that are imposed by the traffic conditions.

4. **Simulated moving bed chromatography** is a technology where several interconnected chromatographic columns are switched periodically against the fluid flow. This allows for a continuous separation with a better performance than the discontinuous single-column chromatography. An efficient operation of SMB chromatography requires a tight control of the process by manipulating the inflow rates in the columns. This process is therefore a typical example of a periodic boundary control hyperbolic system.

Controllability

In this section and in the following one, $Y^* \in \mathbb{R}^n$ is such that none of the eigenvalues of $A(Y^*)$ are 0. After an appropriate linear state transformation, the matrix $A(Y^*)$ can be assumed to be diagonal, with distinct and nonzero entries:

$$A(Y^*) = \operatorname{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n), \quad (10)$$

$$\lambda_1 > \lambda_2 > \cdots > \lambda_m > 0 > \lambda_{m+1} > \cdots > \lambda_n.$$

Let $Y^+ \in \mathbb{R}^m$ and $Y^- \in \mathbb{R}^{n-m}$ be such that $Y^{\mathrm{T}} = (Y^{+\mathrm{T}} \ Y^{-\mathrm{T}})^{\mathrm{T}}$.

For the boundary control system (1), (9), the local controllability issue is to investigate if, starting from a given initial state $Y_0 : x \in$ $[0, L] \mapsto Y_0(x) \in \mathbb{R}^n$, it is possible to reach in time T a desired target state $Y_1 : x \in [0, L] \mapsto Y_1(x) \in \mathbb{R}^n$, with $Y_0(x)$ and $Y_1(x)$ close to Y^*.

Theorem 4 (See Li and Rao 2003) *If there exist control inputs $U^+(t)$ and $U^-(t)$ such that the boundary conditions* (9) *are equivalent to*

$$Y^+(t, 0) = U^+(t), \quad Y^-(t, L) = U^-(t), \tag{11}$$

then the boundary control system (1)*,* (11) *is locally controllable for the C^1-norm if and only if $T > T_c$ with*

$$T_c = \max \left\{ \frac{L}{|\lambda_1|}, \ldots, \frac{L}{|\lambda_n|} \right\}.$$

Feedback Stabilization

For the boundary control system (1), (9), the problem of local boundary feedback stabilization is the problem of finding boundary feedback control actions

$$U(t) = F(Y(t, 0), Y(t, L), Y^*),$$

$$F : \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^p, \tag{12}$$

such that the system trajectory exponentially converges to a desired steady-state Y^* (called *set point*) from any initial condition $Y_0(x)$ close to Y^*. In such case, the set point is said to be exponentially stable.

Theorem 5 (See Coron et al. 2008) *If there exists a boundary feedback $U(t) =$*

$F(Y(t, 0), Y(t, L), Y^*)$ *such that the boundary conditions* (9) *are written in the form*

$$\begin{pmatrix} Y^+(t, 0) \\ Y^-(t, L) \end{pmatrix} = G \begin{pmatrix} Y^+(t, L) \\ Y^-(t, 0) \end{pmatrix}, \quad G(Y^*) = Y^*, \tag{13}$$

then, for the boundary control system (1)*,* (13)*, the set point Y^* is locally exponentially stable for the H^2-norm if*

$$Inf \{\|\Delta G'(Y^*)\Delta^{-1}\|; \ \Delta \in \mathcal{D}\} < 1,$$

where $\| \ \|$ denotes the usual 2-norm of $n \times n$ real matrices, $G'(Y^*)$ denotes the Jacobian matrix of the map G at Y^*, and $\mathcal{D}$ denotes the set of $n \times n$ diagonal real matrices with strictly positive diagonal entries.

For the stabilization in the C^1-norm, another sufficient condition is given in Li (1994).

Summary and Future Directions

With suitable boundary controls, hyperbolic systems can be controlled and stabilized around a desired set point. However, in many situations the hyperbolic model is not sufficient: one needs to add a zero-order term and (1) has to be replaced by

$$Y_t + A(Y)Y_x + C(Y) = 0, \ t \in [0, T], \ x \in [0, L], \tag{14}$$

where $C : \mathbb{R}^n \to \mathbb{R}^n$. This is, for example, the case for the open channels when slope and friction cannot be neglected. Note that the set point Y^* may now depend on x. For the controllability issue, the new term $C(Y)$ turns out to be not essential; see in particular Li (2010). The situation is not the same for the stabilization and only partial results are known. In particular, Coron et al. (2013) uses Krstic's backstepping approach (Krstic and Smyshlyaev 2008) to treat the case $n = 2$ and $m = 1$.

Another important issue for the system (1) is the observability problem: assume that the state is measured on the boundary during the interval of time $[0, T]$, can one recover the initial data?

As shown in Li (2010), this problem has strong connections with the controllability problem and the system (1) is observable if the time T is large enough.

The above results are on smooth solutions of (1). However, the system (1) is known to be well posed in class of BV-solutions (Bounded Variations), with extra conditions (e.g., entropy type); see in particular Bressan (2000). There are partial results on the controllability in this class. See, in particular, Ancona and Marson (1998) and Horsin (1998) for $n = 1$. For $n = 2$, it is shown in Bressan and Coclite (2002) that Theorem 4 no longer holds in general in the BV class. However, there are positive results for important physical systems; see, for example, Glass (2007) for the 1-D isentropic Euler equation.

Boundary Control of Korteweg-de Vries and Kuramoto–Sivashinsky PDEs

Eduardo Cerpa
Departamento de Matemática, Universidad Técnica Federico Santa María, Valparaiso, Chile

Abstract

The Korteweg-de Vries (KdV) and the Kuramoto-Sivashinsky (KS) partial differential equations are used to model nonlinear propagation of one-dimensional phenomena. The KdV equation is used in fluid mechanics to describe waves propagation in shallow water surfaces, while the KS equation models front propagation in reaction-diffusion systems. In this article, the boundary control of these equations is considered

when they are posed on a bounded interval. Different choices of controls are studied for each equation.

Keywords

Controllability; Dispersive equations; Higher-order partial differential equations; Parabolic equations; Stabilizability

Introduction

The Korteweg-de Vries (KdV) and the Kuramoto-Sivashinsky (KS) equations have very different properties because they do not belong to the same class of partial differential equations (PDEs). The first one is a third-order nonlinear dispersive equation

$$y_t + y_x + y_{xxx} + y y_x = 0, \qquad (1)$$

and the second one is a fourth-order nonlinear parabolic equation

$$u_t + u_{xxxx} + \lambda u_{xx} + u u_x = 0, \qquad (2)$$

where $\lambda > 0$ is called the anti-diffusion parameter. However, they have one important characteristic in common. They are both used to model nonlinear propagation phenomena in the space x-direction when the variable t stands for time. The KdV equation serves as a model for waves propagation in shallow water surfaces (Korteweg and de Vries 1895), and the KS equation models front propagation in reaction-diffusion phenomena including some instability effects (Kuramoto and Tsuzuki 1975; Sivashinsky 1977).

From a control point of view, a new common characteristic arises. Because of the order of the spatial derivatives involved, when studying these equations on a bounded interval $[0, L]$, two boundary conditions have to be imposed at the same point, for instance, at $x = L$. Thus, we can consider control systems where we control one boundary condition but not all the boundary data at one endpoint of the interval. This

configuration is not possible for the classical wave and heat equations where at each extreme, only one boundary condition exists and therefore controlling one or all the boundary data at one point is the same.

The KdV equation being of third order in space, three boundary conditions have to be imposed: one at the left endpoint $x = 0$ and two at the right endpoint $x = L$. For the KS equation, four boundary conditions are needed to get a well-posed system, two at each extreme. We will focus on the cases where Dirichlet and Neumann boundary conditions are considered because lack of controllability phenomena appears. This holds for some special values of the length of the interval for the KdV equation and depends on the anti-diffusion coefficient λ for the KS equation.

The particular cases where the lack of controllability occurs can be seen as isolated anomalies. However, those phenomena give us important information on the systems. In particular, any method independent of the value of those constants cannot control or stabilize the system when acting from the corresponding control input where trouble appears. In all of these cases, for both the KdV and the KS equations, the space of uncontrollable states is finite dimensional, and therefore, some methods coming from the control of ordinary differential equations can be applied.

General Definitions

Infinite-dimensional control systems described by PDEs have attracted a lot of attention since the 1970s. In this framework, the state of the control system is given by the solution of an evolution PDE. This solution can be seen as a trajectory in an infinite-dimensional Hilbert space H, for instance, the space of square integrable functions or some Sobolev space. Thus, for any time t, the state belongs to H. Concerning the control input, this is either an internal force distributed in the domain, or a punctual force localized within the domain, or some boundary data as considered in this article. For any time t, the control belongs to a control space U, which can be, for instance,

the space of bounded functions. The main control properties to be mentioned in this article are controllability, stability, and stabilization. A control system is said to be exactly controllable if the system can be driven from any initial state to another one in finite time. This kind of properties holds, for instance, for hyperbolic system as the wave equation. The notion of null-controllability means that the system can be driven to the origin from any initial state. The main example for this property is the heat equation, which presents regularizing effects. Even if the initial data is discontinuous, right after $t = 0$, the solution of the heat equation becomes very smooth, and therefore, it is not possible to impose a discontinuous final state. A system is said to be asymptotically stable if the solutions of the system without any control converge as the time goes to infinity to a stationary solution of the PDE. When this convergence holds with a control depending at each time on the state of the system (feedback control), the system is said to be stabilizable by means of a feedback control law.

All these properties have local versions when a smallness condition for the initial and/or the final state is added. This local character is normally due to the nonlinearity of the system.

The KdV Equation

The classical approach to deal with nonlinearities is first to linearize the system around a given state or trajectory, then to study the linear system and finally to go back to the nonlinear one by means of an inversion argument or a fixed-point theorem. Linearizing (1) around the origin, we get the equation

$$y_t + y_x + y_{xxx} = 0, \tag{3}$$

which can be studied on a finite interval $[0, L]$ under the following three boundary conditions:

$$y(t, 0) = h_1(t), \quad y(t, L) = h_2(t), \quad \text{and}$$
$$y_x(t, L) = h_3(t). \tag{4}$$

Thus, viewing $h_1(t), h_2(t), h_3(t) \in \mathbb{R}$ as controls and the solution $y(t, \cdot) : [0, L] \to \mathbb{R}$ as the state, we can consider the linear control system (3)–(4) and the nonlinear one (1)–(4).

We will report on the role of each input control when the other two are off. The tools used are mainly the duality controllability-observability, Carleman estimates, the multiplier method, the compactness-uniqueness argument, the backstepping method, and fixed-point theorems. Surprisingly, the control properties of the system depend strongly on the location of the controls.

Theorem 1 *The linear KdV system* (3)–(4) *is:*

1. *Null-controllable when controlled from h_1 (i.e., $h_2 = h_3 = 0$) (Glass and Guerrero 2008).*
2. *Exactly controllable when controlled from h_2 (i.e., $h_1 = h_3 = 0$) if and only if L does not belong to a set O of critical lengths defined in Glass and Guerrero (2010).*
3. *Exactly controllable when controlled from h_3 (i.e., $h_1 = h_2 = 0$) if and only if L does not belong to a set of critical lengths N defined in Rosier (1997).*
4. *Asymptotically stable to the origin if $L \notin N$ and no control is applied (Perla Menzala et al. 2002).*
5. *Stabilizable by means of a feedback law using h_1 only (i.e., $h_2 = h_3 = 0$) Cerpa and Coron (2013).*

If $L \in N$ or $L \in O$, one says that L is a critical length since the linear control system (3)–(4) loses controllability properties when only one control input is applied. In those cases, there exists a finite-dimensional subspace of $L^2(0, L)$ which is unreachable from 0 for the linear system. The sets N and O contain infinitely many critical lengths, but they are countable sets.

When one is allowed to use more than one boundary control input, there is no critical spatial domain, and the exact controllability holds for any $L > 0$. This is proved in Zhang (1999) when three boundary controls are used. The case of two control inputs is solved in Rosier (1997), Glass and Guerrero (2010), and Cerpa et al. (2013).

Previous results concern the linearized control system. Considering the nonlinearity yy_x, we obtain the original KdV control system and the following results.

Theorem 2 *The nonlinear KdV system* (1)–(4) *is:*

1. *Locally null-controllable when controlled from h_1 (i.e., $h_2 = h_3 = 0$) (Glass and Guerrero 2008).*
2. *Locally exactly controllable when controlled from h_2 (i.e., $h_1 = h_3 = 0$) if L does not belong to the set O of critical lengths (Glass and Guerrero 2010).*
3. *Locally exactly controllable when controlled from h_3 (i.e., $h_1 = h_2 = 0$). If L belongs to the set of critical lengths N, then a minimal time of control may be required (see Cerpa 2014).*
4. *Asymptotically stable to the origin if $L \notin N$ and no control is applied (Perla Menzala et al. 2002).*
5. *Locally stabilizable by means of a feedback law using h_1 only (i.e., $h_2 = h_3 = 0$) (Cerpa and Coron 2013).*

Item 3 in Theorem 2 is a truly nonlinear result obtained by applying a power series method introduced in Coron and Crépeau (2004). All other items are implied by perturbation arguments based on the linear control system. The related control system formed by (1) with boundary controls

$$y(t, 0) = h_1(t), \quad y_x(t, L) = h_2(t), \quad \text{and}$$
$$y_{xx}(t, L) = h_3(t), \tag{5}$$

is studied in Cerpa et al. (2013), and the same phenomenon of critical lengths appears.

The KS Equation

Applying the same strategy than for KdV, we linearize (2) around the origin to get the equation

$$u_t + u_{xxxx} + \lambda u_{xx} = 0, \tag{6}$$

which can be studied on the finite interval $[0, 1]$ under the following four boundary conditions:

$$u(t, 0) = v_1(t), \quad u_x(t, 0) = v_2(t),$$
$$u(t, 1) = v_3(t), \quad \text{and} \quad u_x(t, 1) = v_4(t). \tag{7}$$

Thus, viewing $v_1(t), v_2(t), v_3(t), v_4(t) \in \mathbb{R}$ as controls and the solution $u(t, \cdot) : [0, 1] \to \mathbb{R}$ as the state, we can consider the linear control system (6)–(7) and the nonlinear one (2)–(7). The role of the parameter λ is crucial. The KS equation is parabolic and the eigenvalues of system (6)–(7) with no control ($v_1 = v_2 = v_3 = v_4 = 0$) go to $-\infty$. If λ increases, then the eigenvalues move to the right. When $\lambda > 4\pi^2$, the system becomes unstable because there are a finite number of positive eigenvalues. In this unstable regime, the system loses control properties for some values of λ.

Theorem 3 *The linear KS control system* (6)–(7) *is:*
1. *Null-controllable when controlled from v_1 and v_2 (i.e., $v_3 = v_4 = 0$). The same is true when controlling v_3 and v_4 (i.e., $v_1 = v_2 = 0$) (Cerpa and Mercado 2011; Lin Guo 2002).*
2. *Null-controllable when controlled from v_2 (i.e., $v_1 = v_2 = v_3 = 0$) if and only if λ does not belong to a countable set M defined in Cerpa (2010).*
3. *Asymptotically stable to the origin if $\lambda < 4\pi^2$ and no control is applied (Liu and Krstic 2001).*
4. *Stabilizable by means of a feedback law using v_2 only (i.e., $v_2 = v_3 = v_4 = 0$) if and only if $\lambda \notin M$ (Cerpa 2010).*

In the critical case $\lambda \in M$, the linear system is not null-controllable anymore if we control v_2 only (item 2 in Theorem 3). The space of noncontrollable states is finite dimensional. To obtain the null-controllability of the linear system in these cases, we have to add another control. Controlling with v_2 and v_4 does not improve the situation in the critical cases. Unlike that, the system becomes null-controllable if we can act on v_1 and v_2. This result with two input controls has been proved in Lin Guo (2002) for the case $\lambda = 0$ and in Cerpa and Mercado (2011) in the general case (item 1 in Theorem 3).

It is known from Liu and Krstic (2001) that if $\lambda < 4\pi^2$, then the system is exponentially stable in $L^2(0, 1)$. On the other hand, if $\lambda = 4\pi^2$, then zero becomes an eigenvalue of the system, and therefore the asymptotic stability fails. When $\lambda > 4\pi^2$, the system has positive eigenvalues and becomes unstable. In order to stabilize this system, a finite-dimensional-based feedback law can be designed by using the pole placement method (item 4 in Theorem 3).

Previous results concern the linearized control system. If we add the nonlinearity uu_x, we obtain the original KS control system and the following results.

Theorem 4 *The KS control system* (2)–(7) *is:*
1. *Locally null-controllable when controlled from v_1 and v_2 (i.e., $v_3 = v_4 = 0$). The same is true when controlling v_3 and v_4 (i.e., $v_1 = v_2 = 0$) (Cerpa and Mercado 2011).*
2. *Asymptotically stable to the origin if $\lambda < 4\pi^2$ and no control is applied (Liu and Krstic 2001).*

There are less results for the nonlinear systems than for the linear one. This is due to the fact that the spectral techniques used to study the linear system with only one control input are not robust enough to deal with perturbations in order to address the nonlinear control system.

Summary and Future Directions

The KdV and the KS equations possess both noncontrol results when one boundary control input is applied. This is due to the fact that both are higher-order equations, and therefore, when posed on a bounded interval, more than one boundary condition should be imposed at the same point. The KdV equation is exactly controllable when acting from the right and null-controllable when acting from the left. On the other hand, the KS equation, being parabolic as the heat equation, is not exactly controllable but null-controllable. Most of the results are implied by the behaviors of the corresponding linear system, which are very well understood.

For the KdV equation, the main directions to investigate at this moment are the controllability and the stability for the nonlinear equation in critical domains. Among others, some questions concerning controllability, minimal time of control, and decay rates for the stability are open. Regarding the KS equation, there are few results for the nonlinear system with one control input even if we are not in a critical value of the anti-diffusion parameter. In the critical cases, the controllability and stability issues are wide open.

In general, for PDEs, there are few results about delay phenomena, output feedback laws, adaptive control, and other classical questions in control theory. The existing results on these topics mainly concern the more popular heat and wave equations. As KdV and KS equations are one dimensional in space, many mathematical tools are available to tackle those problems. For all that, to our opinion, the KdV and KS equations are excellent candidates to continue investigating these control properties in a PDE framework.

Abstract

We review several universal lower bounds on
statistical estimation, including deterministic
bounds on unbiased estimators such as Cramér-
Rao bound and Barankin-type bound, as well as
Bayesian bounds such as Ziv-Zakai bound. We
present explicit forms of these bounds, illustrate
their usage for parameter estimation in Gaussian
additive noise, and compare their tightness.

Keywords

Barankin-type bound; Cramér-Rao bound;
Mean-squared error; Statistical estimation;
Ziv-Zakai bound

Introduction

Statistical estimation involves inferring the values
of parameters specifying a statistical model from
data. The performance of a particular statistical
algorithm is measured by the error between the
true parameter values and those estimated by the
algorithm. However, explicit forms of estimation
error are usually difficult to obtain except for
the simplest statistical models. Therefore, per-
formance bounds are derived as a way of quan-
tifying estimation accuracy while maintaining
tractability.

In many cases, it is beneficial to quantify
performance using universal bounds that are in-
dependent of the estimation algorithms and rely
only upon the model. In this regard, universal
lower bounds are particularly useful as it provides
means to assess the difficulty of performing es-
timation for a particular model and can act as
benchmarks to evaluate the quality of any algo-
rithm: the closer the estimation error of the algo-
rithm to the lower bound, the better the algorithm.
In the following, we review three widely used
universal lower bounds on estimation: Cramér-
Rao bound (CRB), Barankin-type bound (BTB),
and Ziv-Zakai bound (ZZB). These bounds find
numerous applications in determining the per-
formance of sensor arrays, radar, and nonlinear
filtering; in benchmarking various algorithms;
and in optimal design of systems.

Statistical Model and Related Concepts

To formalize matters, we define a statistical
model for estimation as a family of parameterized
probability density functions in $\mathbb{R}^N$: $\{p(x; \theta) :
\theta \in \Theta \subset \mathbb{R}^d\}$. We observe a realization of
$x \in \mathbb{R}^N$ generated from a distribution $p(x; \theta)$,
where $\theta \in \Theta$ is the true parameter to be
estimated from data x. Though we assume a
single observation x, the model is general enough
to encompass multiple independent, identically
distributed samples (i.i.d.) by considering the
joint probability distribution.

An estimator of θ is a measurable function of
the observation $\hat{\theta}(x) : \mathbb{R}^N \rightarrow \Theta$. An unbiased
estimator is one such that

$$\mathbb{E}_\theta \left\{ \hat{\theta}(x) \right\} = \theta, \forall \theta \in \Theta. \quad (1)$$

Here we used the subscript θ to emphasize that the expectation is taken with respect to $p(x; \theta)$. We focus on the performance of unbiased estimators in this entry. There are various ways to measure the error of the estimator $\hat{\theta}(x)$. Two typical ones are the error covariance matrix:

$$\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} = \text{Cov}(\hat{\theta}), \quad (2)$$

where the equation holds only for unbiased estimators, and the mean-squared error (MSE):

$$\mathbb{E}_\theta \left\{ \|\hat{\theta}(x) - \theta\|_2^2 \right\} = \text{trace} \left(\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta) \right. \right.$$
$$\left. \left. (\hat{\theta} - \theta)^T \right\} \right). \quad (3)$$

Example 1 (Signal in additive Gaussian noise (SAGN)) To illustrate the usage of different estimation bounds, we use the following statistical model as a running example:

$$x_n = s_n(\theta) + w_n, n = 0, \dots, N - 1. \quad (4)$$

Here $\theta \in \Theta \subset \mathbb{R}$ is a scalar parameter to be estimated and the noise w_n follows i.i.d. Gaussian distribution with mean 0 and *known* variance σ^2. Therefore, the density function for x is

$$p(x; \theta)$$
$$= \prod_{n=0}^{N-1} \frac{1}{\sqrt{2\pi}\sigma} \exp \left\{ -\frac{(x_n - s_n(\theta))^2}{2\sigma^2} \right\}$$
$$= \frac{1}{(\sqrt{2\pi}\sigma)^N} \exp \left\{ -\sum_{n=0}^{N-1} \frac{(x_n - s_n(\theta))^2}{2\sigma^2} \right\}.$$

In particular, we consider the frequency estimation problem where $s_n(\theta) = \cos(2\pi n\theta)$ with $\Theta = [0, \frac{1}{4})$.

Cramér-Rao Bound

The Cramér-Rao bound (CRB) (Kay 2001a; Stoica and Nehorai 1989; Van Trees 2001) is arguably the most well-known lower bounds on

estimation. Define the Fisher information matrix $I(\theta)$ via

$$I_{i,j}(\theta) = \mathbb{E}_\theta \left\{ \frac{\partial}{\partial \theta_i} \log p(x; \theta) \frac{\partial}{\partial \theta_j} \log p(x; \theta) \right\}$$
$$= -\mathbb{E}_\theta \left\{ \frac{\partial^2}{\partial \theta_i \partial \theta_j} \log p(x; \theta) \right\}.$$

Then for *any* unbiased estimator $\hat{\theta}$, the error covariance matrix is bounded by

$$\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} \succeq [I(\theta)]^{-1}, \quad (5)$$

where $A \succeq B$ for two symmetric matrices means $A - B$ is positive semidefinite. The inverse of the Fisher information matrix $\text{CRB}(\theta) = [I(\theta)]^{-1}$ is called the Cramér-Rao bound.

When θ is scalar, $I(\theta)$ measures the expected sensitivity of the density function with respect to changes in the parameter. A density family that is more sensitive to parameter changes (larger $I(\theta)$) will generate observations that look more different when the true parameter varies, making it easier to estimate (smaller error).

Example 2 For the SAGN model (4), the CRB is

$$\text{CRB}(\theta) = I(\theta)^{-1} = \frac{\sigma^2}{\sum_{n=0}^{N-1} \left[\frac{\partial s_n(\theta)}{\partial \theta} \right]^2}. \quad (6)$$

The inverse dependence on the ℓ_2 norm of signal derivative suggests that signals more sensitive to parameter change are easier to estimate.

For the frequency estimation problem with $s_n(\theta) = \cos(2\pi n\theta)$, the CRB as a function of θ is plotted in Fig. 1.

There are many modifications of the basic CRB such as the posterior CRB (Tichavsky et al. 1998; Van Trees 2001), the hybrid CRB (Rockah and Schultheiss 1987), the modified CRB (D'Andrea et al. 1994), the concentrated CRB (Hochwald and Nehorai 1994), and constrained CRB (Gorman and Hero 1990; Marzetta 1993; Stoica and Ng 1998). The posterior CRB takes into account the prior information of the parameters when they are modeled as random
Bounds on Estimation, Fig. 1 Cramér-Rao bound on frequency estimation: $N = 5$ vs. $N = 10$

variables, while the hybrid CRB considers the case that the parameters contain both random and deterministic parts. The modified CRB and the concentrated CRB focus on handling nuisance parameters in a tractable manner. The application of the these CRBs requires a regular parameter space (e.g., an open set in $\mathbb{R}^d$). However, in many case, the parameter space Θ is a low-dimensional manifolds in $\mathbb{R}^d$ specified by equalities and inequalities. In this case, the constrained CRB provides tighter lower bounds by incorporating knowledge of the constraints.

Barankin Bound

CRB is a local bound in the sense that it involves only local properties (the first or second order derivatives) of the log-likelihood function. So if two families of log-likelihood functions coincide at a region near θ^0, the CRB at θ^0 would be the same, even if they are drastically different in other regions of the parameter space.

However, the entire parametric space should play a role in determining the difficulty of parameter estimation. To see this, imagine that there are two statistical models. In the first model there is another point $\theta^1 \in \Theta$ such that the likelihood

family $p(x; \theta)$ behaves similarly around θ^0 and θ^1, but these two points are not in neighborhoods of each other. Then it would be difficult to distinguish these two points for any estimation algorithm, and the estimation performance for the first statistical model would be bad (an extreme case is $p(x; \theta^0) \equiv p(x; \theta^1)$ in which case the model is non-identifiable; more discussions on identifiability and Fisher information matrix can be found in Hochwald and Nehorai (1997)). In the second model, we remove the point θ^1 and its near neighborhood from Θ, then the performance should get better. However, CRB for both models would remain the same whether we exclude θ^1 from Θ or not. As a matter of fact, CRB(θ^0) uses only the fact that the estimator is unbiased in a neighborhood of the true parameter θ^0.

Barankin bound addresses CRB's shortcoming of not respecting the global structure of the statistical model by introducing finitely many test points $\{\theta^i, i = 1, \ldots, M\}$ and ensures that the estimator is unbiased at the neighborhood of θ^0 as well as these test points (Forster and Larzabal 2002). The original Barankin bound (Barankin 1949) is derived for scalar parameter $\theta \in \Theta \subset \mathbb{R}$ and any unbiased estimator $\widehat{g(\theta)}$ for a function $g(\theta)$:

$$\mathbb{E}_\theta(\widehat{g(\theta)} - g(\theta))^2 \geq \sup_{M, \theta^i, a^i}$$

$$\frac{\left[\sum_{m=1}^M a^i (g(\theta^i) - g(\theta)) \right]^2}{\mathbb{E}_\theta \left[\sum_{m=1}^M a^i \frac{p(x; \theta^i)}{p(x; \theta)} \right]^2} \quad (7)$$
Using (7), we can derive a Barankin-type bound on the error covariance matrix of any unbiased estimator $\hat{\theta}(x)$ for a vector parameter $\theta \in \Theta \subset \mathbb{R}^d$ (Forster and Larzabal 2002):

$$\mathbb{E}_\theta \left\{ (\hat{\theta} - \theta)(\hat{\theta} - \theta)^T \right\} \geq \Phi(B - 11^T)^{-1}\Phi^T, \quad (8)$$

where the matrices are defined via

$$B_{i,j} = \mathbb{E}_\theta \left\{ \frac{p(x; \theta^i)}{p(x; \theta)} \frac{p(x; \theta^j)}{p(x; \theta)} \right\}, 1 \leq i, j \leq M,$$

$$\Phi = \begin{bmatrix} \theta^1 - \theta \cdots \theta^M - \theta \end{bmatrix}$$

Bounds on Estimation, Fig. 2 Cramér-Rao bound vs. Barankin-type bound on frequency estimation when $\theta^0 = 0.1$. The BTB is obtained using $M = 10$ uniform random points

and 1 is the vector in $\mathbb{R}^M$ with all ones. Note that we have used θ^i with a superscript to denote different points in Θ, while θ_i with a subscript to denote the ith component of a point θ.

Since the bound (8) is valid for any M and any choice of test points $\{\theta^i\}$, we obtain the tightest bound by taking the supremum over all finite families of test points. Note that when we have d test points that approach θ in d linearly independent directions, the Barankin-type bound (8) converges to the CRB. If we have more than d test points, however, the Barankin-type bound is always not worse than the CRB. Particularly, the Barankin-type bound is much tighter in the regime of low signal-to-noise ratio (SNR) and small number of measurements, which allows one to investigate the "threshold" phenomena as shown in the next example.

Example 3 For the SAGN model, if we have M test points, the elements of matrix B are of the following form:

$$B_{i,j} = \exp\left\{\frac{1}{\sigma^2}\sum_{n=0}^{N-1}[s_n(\theta^i) - s_n(\theta)]\right.$$

$$\left.[s_n(\theta^j) - s_n(\theta)]\right\}$$

In most cases, it is extremely difficult to derive an analytical form of the Barankin bound by optimizing with respect to M and the test points $\{\theta^j\}$. In Fig. 2, we plot the Barankin-type bounds for $s_n(\theta) = \cos(2\pi n\theta)$ for $M = 10$ randomly selected test points. We observe that Barankin-type bound is tighter than the CRB when SNR is small. There is a SNR region around 0 dB that the Brankin-type bound drops drastically. This is usually called the "threshold" phenomenon. Practical systems operate much better in the region above the threshold.

The basic CRB and BTB belong to the family of deterministic "covariance inequality" bounds in the sense that the unknown parameter is assumed to be a *deterministic* quantity (as opposed to a *random* quantity). Additionally, both bounds work only for unbiased estimators, making them inappropriate performance indicators for biased estimators such as many regularization-based estimators.

Ziv-Zakai Bound

In this section, we introduce the Ziv-Zakai bound (ZZB) (Bell et al. 1997) that is applicable to any estimator (not necessarily unbiased). Unlike the CRB and BTB, the ZZB is a Bayesian bound and the errors are averaged by the prior distribution $p_\theta(\phi)$ of the parameter. For any $a \in \mathbb{R}^d$, the ZZB states that

$$a^T\mathbb{E}\left\{(\hat{\theta}(x) - \theta)(\hat{\theta}(x) - \theta)^T\right\}a \geq$$

$$\frac{1}{2}\int_0^\infty \mathcal{V}\left\{\max_{\delta:a^T\delta=h}\left[\int_{\mathbb{R}^d}(p_\theta(\phi) + p_\theta(\phi + \delta))\right.\right.$$

$$\left.\left. times P_{\min}(\phi, \phi + \delta)d\phi\right]\right\}hdh,$$

where the expectation is taken with respect to the joint disunity $p(x;\theta)p_\theta(\phi)$, $\mathcal{V}\{q(h)\} = \max_{r\geq 0}q(h + r)$ is the valley-filling function, and $P_{\min}(\phi, \phi + \delta)$ is the minimal probability of error for the following binary hypothesis testing problem:

$$H_0 : \theta = \phi; \qquad x \sim p(x;\phi)$$

$$H_1 : \theta = \phi + \delta; \; x \sim p(x; \phi + \delta)$$

with

$$\Pr(H_0) = \frac{p_\theta(\phi)}{p_\theta(\phi) + p_\theta(\phi + \delta)}$$

$$\Pr(H_1) = \frac{p_\theta(\phi + \delta)}{p_\theta(\phi) + p_\theta(\phi + \delta)}.$$

Example 4 For the ASGN model, we assume a uniform prior probability, i.e., $p_\theta(\phi) = 4, \phi \in [0, 1/4)$. The ZZB simplifies to

$$\mathbb{E}\left\{\|\hat{\theta}(x) - \theta\|_2^2\right\} \geq$$

$$\frac{1}{2} \int_0^{\frac{1}{4}} \mathcal{V}\left\{\left[\int_0^{\frac{1}{4}-h} 8 P_{\min}(\phi, \phi + h)d\phi\right]\right\} h\,dh.$$

The binary hypothesis testing problem is to decide which one of two signals is buried in additive Gaussian noise. The optimal detector with minimal probability of error is the minimum distance receiver (Kay 2001b), and the associated probability of error is

$$P_{\min}(\phi, \phi + h)$$

$$= Q\left(\frac{1}{2}\sqrt{\frac{\sum_{n=0}^{N-1}(s_n(\phi) - s_n(\phi + h))^2}{\sigma^2}}\right),$$

where $Q(h) = \int_h^\infty \frac{1}{\sqrt{2\pi}} e^{-\frac{t^2}{2}} dt$. For the frequency estimation problem, we numerically estimate the integral and plot the resulting ZZB in Fig. 3 together with the mean-squared error for the maximum likelihood estimator (MLE).

Summary and Future Directions

We have reviewed several important performance bounds on statistical estimation problems, particularly, the Cramér-Rao bound, the Barankin-type bound, and the Ziv-Zakai bound. These bounds provide a universal way to quantify
Bounds on Estimation, Fig. 3 Ziv-Zakai bound vs. maximum likelihood estimator for frequency estimation

the performance of statistically modeled physical systems that is independent of any specific algorithm.

Future directions of performance bounds on estimation include deriving tighter bounds, developing computational schemes to approximate existing bounds in a tractable way, and applying them to practical problems.

Building Control Systems

James E. Braun
Purdue University, West Lafayette, IN, USA

Abstract

This entry provides an overview of systems and issues related to providing optimized controls for commercial buildings. It includes a description of the evolution of the control systems over time, typical equipment and control variables, typical two-level hierarchal structure for feedback and supervisory control, definition of the optimal supervisory control problem, references to typical heuristic control approaches, and a description of current and future developments.

Keywords

Building automation systems (BAS); Cooling plant optimization; Energy management and controls systems (EMCS); Intelligent building controls

Introduction

Computerized control systems were developed in the 1980s for commercial buildings and are typically termed energy management and control systems (EMCS) or building automation systems (BAS). They have been most successfully applied to large commercial buildings that have hundreds of building zones and thousands of control points. Less than about 15 % of commercial buildings have EMCS, but they serve about 40 % of the floor area. Small commercial buildings tend not to have an EMCS, although there is a recent trend towards the use of wireless thermostats with cloud-based energy management solutions.

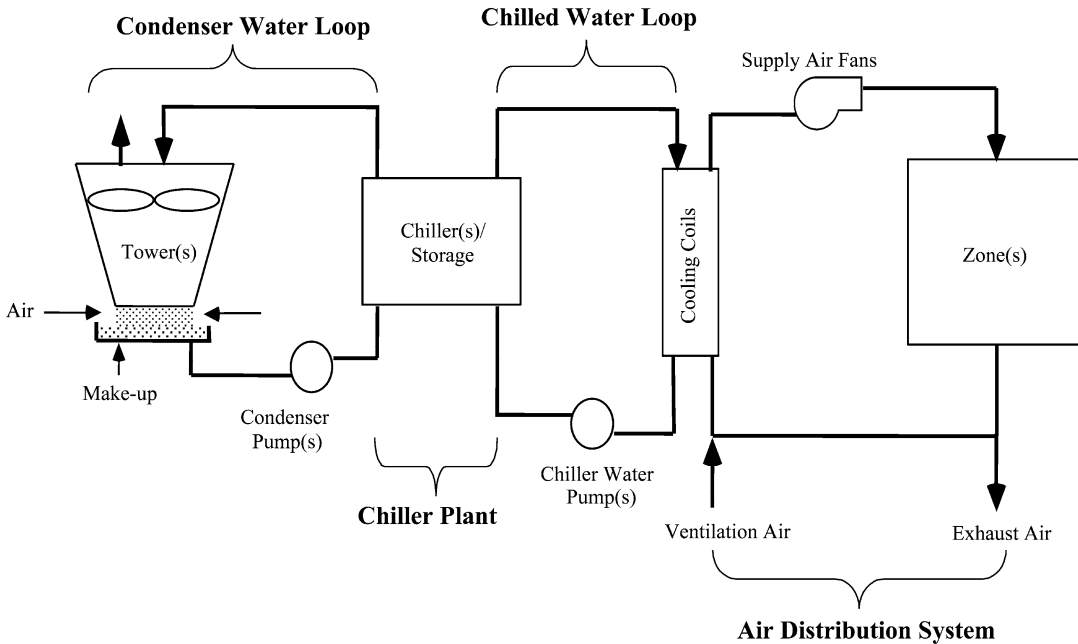
EMCS architectures for buildings have evolved from centralized to highly distributed systems as depicted in Fig. 1 in order to reduce
Building Control Systems, Fig. 1 Evolution from centralized to distributed network architectures

wiring costs and provide more modular solutions. The development of open communications protocols, such as BACNet, has enabled the use of distributed control devices from different vendors and improved the cost-effectiveness of ECMS. There has also been a recent trend towards the use of existing enterprise networks to reduce system installed costs and to more easily allow remote access and control from any Internet accessible device.

An EMCS for a large commercial building can automate the control of many of the building and system functions, including scheduling of lights and zone thermostat settings according to occupancy patterns. Security and fire safety systems tend to be managed using separate systems. In addition to scheduling, an EMCS manages the control of individual equipment and subsystems that provide heating, ventilation, and air conditioning of the building (HVAC). This control is achieved using a two-level hierarchical structure of local-loop and supervisory control. Local-loop control of individual set points is typically implemented using individual proportional-integral (PI) feedback algorithms that manipulate individual actuators in response to deviations from the set points. For example, supply air temperature from a cooling coil is controlled by adjusting a valve opening that provides chilled water to the coil. The second level of supervisory control specifies the set points and other modes of operation that depend on time and external conditions.

Each local-loop feedback controller acts independently, but their performance can be coupled to other local-loop controllers if not tuned appropriately. Adaptive tuning algorithms have been developed in recent years to enable controllers to automatically adjust to changing weather and load conditions. There are typically a number of degrees of freedom in adjusting supervisory control set points over a wide range while still achieving adequate comfort conditions. Optimal control of supervisory set points involves minimizing a cost function with respect to the free variables and subject to constraints. Although model-based, control optimization approaches are not typically employed in buildings, they have been used to inform the development and assessment of some heuristic control strategies. Most commonly, strategies for adjusting supervisory control variables are established at the control design phase based on some limited analysis of the HVAC system and specified as a sequence of operations that is programmed into the EMCS.

Systems, Equipment, and Controls

The greatest challenges and opportunities for optimizing supervisory control variables exist for


Building Control Systems, Fig. 2 Schematic of a chilled water cooling system

centralized cooling systems that are employed in large commercial buildings because of the large number of control variables and degrees of freedom along with utility rate incentives. A simplified schematic of a typical centralized cooling plant is shown in Fig. 2 with components grouped under air distribution, chilled water loop, chiller plant, and condenser water loop.

Typical **air distribution systems** include VAV (variable-air volume) boxes within the zones, air-handling units, ducts, and controls. An air-handling unit (AHU) provides the primary conditioning, ventilation, and flow of air and includes cooling and heating coils, dampers, fans, and controls. A single air handler typically serves many zones and several air handlers are utilized in a large commercial building. For each AHU, outdoor ventilation air is mixed with return air from the zones and fed to the cooling coil. Outdoor and return air dampers are typically controlled using an economizer control that selects between minimum and maximum ventilation air depending upon the condition of the outside air. The cooling coil provides both cooling and dehumidification of the process air. The air outlet temperature from

the coil is controlled with a local feedback controller that adjusts the flow of water using a valve. A supply fan and return fan (not shown in Fig. 2) provide the necessary airflow to and from the zones. With a VAV system, zone temperature set points are regulated using a feedback controller applied to dampers within the VAV boxes. The overall air flow provided by the AHU is typically controlled to maintain a duct static pressure set point within the supply duct.

The **chilled water loop** communicates between the cooling coils within the AHUs and chillers that provide the primary source for cooling. It consists of pumps, pipes, valves, and controls. Primary/secondary chilled water systems are commonly employed to accommodate variable-speed pumping. In the primary loop, fixed-speed pumps are used to provide relatively constant chiller flow rates to ensure good performance and reduce the risk of evaporator tube freezing. Individual pumps are typically cycled on and off with a chiller that it serves. The secondary loop incorporates one or more variable-speed pumps that are typically controlled to maintain a set point for chilled water

loop differential pressure between the building supplies and returns.

The primary source of cooling for the system is typically provided by one or more **chillers** that are arranged in parallel and have dedicated pumps. Each chiller has an on-board local-loop feedback controller that adjusts its cooling capacity to maintain a specified set point for chilled water supply temperature. Additional chiller control variables include the number of chillers operating and the relative loading for each chiller. The relative loading can be controlled for a given total cooling requirement by utilizing different chilled water supply set points for constant individual flow or by adjusting individual flows for identical set points. Chillers can be augmented with thermal storage to reduce the amount of chiller power required during occupied periods in order to reduce on-peak energy and power demand costs. The thermal storage medium is cooled during the unoccupied, nighttime period using the chillers when electricity is less expensive. During occupied times, a combination of the chillers and storage are used to meet cooling requirements. Control of thermal storage is defined by the manner in which the storage medium is charged and discharged over time.

The **condenser water loop** includes cooling towers, pumps, piping, and controls. Cooling towers reject energy to the ambient air through heat transfer and possibly evaporation (for wet towers). Larger systems tend to have multiple cooling towers with each tower having multiple cells that share a common sump with individual fans having two or more speed settings. The number of operating cells and tower fan speeds are often controlled using a local-loop feedback controller that maintains a set point for the water temperature leaving the cooling tower. Typically, condenser water pumps are dedicated to individual chillers (i.e., each pump is cycled on and off with a chiller that it serves).

In order to better understand building control variables, interactions, and opportunities, consider how controls change in response to increasing building cooling requirements for the system of Fig. 2. As energy gains to the zones increase, zone temperatures rise in the absence of any control changes. However, zone feedback controllers respond to higher temperatures by increasing VAV box airflow through increased damper openings. This leads to reduced static pressure in the primary supply duct, which causes the AHU supply fan controller to create additional airflow. The greater airflow causes an increase in supply air temperatures leaving the cooling coils in the absence of any additional control changes. However, the supply air temperature feedback controllers respond by opening the cooling coil valves to increase water flow and the heat transfer to the chilled water (the cooling load). For variable-speed pumping, a feedback controller would respond to decreasing pressure differential by increasing the pump speed. The chillers would then experience increased loads due to higher return water temperature and/or flow rate that would lead to increases in chilled water supply temperatures. However, the chiller controllers would respond by increasing chiller cooling capacities in order to maintain the chilled water supply set points (and match the cooling coil loads). In turn, the heat rejection to the condenser water loop would increase to balance the increased energy removed by the chiller, which would increase the temperature of water leaving the condenser. The temperature of water leaving the cooling tower would then increase due to an increase in its energy water temperature. However, a feedback controller would respond to the higher condenser water supply temperature and increase the tower airflow. At some load, the current set of operating chillers would not be sufficient to meet the load (i.e., maintain the chilled water supply set points) and an additional chiller would need to be brought online.

This example illustrated how different local-loop controllers might respond to load changes in order to maintain individual set points. Supervisory control might change these set points and modes of operation. At any given time, it is possible to meet the cooling needs with any number of different modes of operation and set points leading to the potential for control optimization to minimize an objective function.

The system depicted in Fig. 2 and described in the preceding paragraphs represents one of

many different types of systems employed in commercial buildings. Medium-sized commercial buildings often employ multiple direct expansion (DX) cooling systems where refrigerant flows between each AHU and an outdoor condensing unit that employs variable capacity compressors. The compressor capacity is typically controlled to maintain a supply air temperature set point, which is still available as a supervisory control variable. However, the other condensing unit controls (e.g., condensing fans, expansion valve) are typically prepackaged with the unit and not available to the EMCS. For smaller commercial buildings, rooftop units (RTUs) are typically employed that contain a prepackaged AHU, refrigeration cycle, and controls. Each RTU directly cools the air in a portion of the building in response to an individual thermostat. The capacity control is typically on/off staging of the compressor and constant volume air flow is mostly commonly employed. In this case, the only free supervisory control variables are the thermostat set points. In general, the degrees of freedom for supervisory control decrease in going from chilled water cooling plants to DX system to RTUs. In addition, the utility rate incentives for taking advantage of thermal storage and advanced controls are greater for large commercial building applications.

Optimal Supervisory Control

In commercial buildings, it is common to have electric utility rates that have energy and demand charges that vary with time of use. The different rate periods can often include on-peak, off-peak, and mid-peak periods. For this type of rate structure, the time horizon necessary to truly minimize operating costs extends over the entire month. In order to better understand the control issues, consider the general optimal control problem for minimizing monthly electrical utility charges associated with operating an all-electric cooling system in the presence of time-of-use and demand charges. The dynamic optimization involves minimizing

$$J = \sum_{p=1}^{\text{rate periods}} J_p + R_{d,a} \max [P_k]_{k=1 \, to \, N_{\text{month}}}$$

with respect to a trajectory of controls $\vec{u}_k, k = 1 \, to \, N_{\text{month}}$, $\vec{M}_k, k = 1 \, to \, N_{\text{month}}$ where

$$J_p = R_{e,p} \sum_{j=1}^{N_p} P_{p,j} \Delta t + R_{d,p} \max \left[P_{p,j} \right]_{j=1 \, to \, N_p}$$

with the optimization subject to the following general constraints

$$P_k = P(\vec{f}_k, \vec{u}_k, \vec{M}_k)$$
$$\vec{x}_k = x(\vec{x}_{k-1}, \vec{f}_k, \vec{u}_k, \vec{M}_k)$$
$$\vec{u}_{k,\min} \leq \vec{u}_k \leq \vec{u}_{k,\max}$$
$$\mathbf{x}_{k,\min} \leq \mathbf{x}_k \leq \mathbf{x}_{k,\max} \, \vec{y}_k (\vec{f}_k, \vec{u}_k, \vec{M}_k) \leq \vec{y}_{k,\max}$$
$$(\vec{f}_k, \vec{u}_k, \vec{M}_k)$$

where J is the monthly electrical cost (\$), the subscript p denotes that a quantity is limited to a particular type of rate period p (e.g., on-peak, off-peak, mid-peak), $R_{d,a}$ is an anytime demand charge (\$/kW) that is applied to the maximum power consumption occurring over the month P_k is average building power (kW) for stage k within the month, N_{month} is the number of stages in the month, $R_{e,p}$ is the unit cost of electrical energy (\$/kWh) for rate period type p, Δt is the length of the stage (h), N_p is the number of stages within rate period type p in the month, $R_{d,p}$ is a rate period specific demand charge (\$/kW) that is applied to the maximum power consumption occurring during the month within rate period p, $\mathbf{f}_k$ is a vector of uncontrolled inputs that affect building power consumption (e.g., weather, internal gains), $\vec{u}_k$ is a vector of continuous supervisory control variables (e.g., supply air temperature set point), $\mathbf{M}_k$ is a vector of discrete supervisory control variables (chiller on/off controls), $\mathbf{x}_k$ is a vector of state variables, $\mathbf{y}_k$ is a vector of outputs, and subscripts min and max denote minimum and maximum allowable values.

The state variables could characterize the state of a storage device such as a chilled water or

ice storage tank. In this case, the states would be constrained between limits associated with the device's practical storage potential. When variations in zone temperature set points are considered within an optimization, then state variables associated with the distributed nature of energy storage within the building structure are important to consider. The outputs are additional quantities of interest, such as equipment cooling capacities, occupant comfort conditions, etc., that often need to be constrained. In order to implement a model-based predictive control scheme, it would be necessary to have models for the building power, state variables, and outputs in terms of the control and uncontrolled variables. The uncontrolled variables would generally include weather (temperature, humidity, solar radiation) and internal gains due to lights and occupants, etc., that would need to be forecasted over a prediction horizon.

It is not feasible to solve this type of monthly optimization problem for buildings for a variety of reasons, including that forecasting of uncontrolled inputs beyond a day is unreliable. Also, it is very costly to develop the models necessary to implement a model-based control approach of this scale for a particular building. However, it is instructive to consider some special cases that have led to some practical control approaches. First of all, consider the problem of optimizing only the cooling plant supervisory control variables when energy storage effects are not important. This is typically the case for typical systems that do not include ice or chilled water storage. For this scenario, the future does not matter and the problem can be reformulated as a static optimization problem, such that for each stage k the goal is to minimize the building power consumption, $J = P_k$, with respect to the current supervisory control variables, $\vec{u}_k$ and $\mathbf{M}_k$, and subject to constraints. ASHRAE (2011) presents a number of heuristic approaches for adjusting supervisory control variables that have been developed through consideration of this type of optimization problem. This includes algorithms for adjusting cooling tower fan settings, chilled water supply air set points, and chiller sequencing and loading.

Other heuristic approaches have been developed (e.g., ASHRAE 2011; Braun 2007) for controlling the charging and discharging of ice or chilled water storage that were derived from a daily optimization formulation. For the case of real-time pricing of energy, heuristic charging and discharging strategies were derived from minimizing a daily cost function

$$J_{\mathrm{day}} = \sum_{k=1}^{N_{\mathrm{day}}} R_{e,k} P_k \Delta t$$

with respect to a trajectory of charging and discharging rates, subject to a constraint of equal beginning and ending storage states along with other constraints previously described. For the case of typical time-of-use (e.g., on-peak, off-peak) or real-time pricing energy charges with demand charges, heuristic strategies have been developed based on the same form of the daily cost function above with an added demand cost constraint $R_{d,k} P_k \leq TDC$ where TDC is a target demand cost that is set heuristically at the beginning of each billing period and updated at each stage as $TDC_{k+1} = \max(TDC_k, R_{d,k} P_k)$. The heuristic storage control strategies can be readily combined with heuristic strategies for the cooling plant components.

There has been a lot of interest in developing practical methods for dynamic control of zone temperature set points within the bounds of comfort in order to minimize the utility costs. However, this is a very difficult problem and so this remains in the research realm for the time being with limited commercial success.

Summary and Future Directions

Although there is great opportunity for reducing energy use and operating costs in buildings through optimal supervisory control, it is rarely implemented in practice because of high costs associated with engineering site-specific solutions. Current efforts are underway to develop scalable approaches that utilize general methods for configuring and learning models needed to implement model-based predictive control (MPC).

The current thinking is that solutions for optimal supervisory control will be implemented in the cloud and overlay on existing building automation systems (BMS) through the use of universal middleware. This will reduce the cost of implementation compared to programming within existing BMS. There is also a need to reduce the cost of the additional sensors needed to implement MPC. One approach involves the use of virtual sensors that employ models with low-cost sensor inputs to provide higher value information that would normally require expensive sensors to obtain.

Cascading Network Failure in Power Grid Blackouts

Ian Dobson
Iowa State University, Ames, IA, USA

Abstract

Cascading failure consists of complicated sequences of dependent failures and can cause large blackouts. The emerging risk analysis, simulation, and modeling of cascading blackouts are briefly surveyed, and key references are suggested.

Keywords

Branching process; Dependent failures; Outage; Power law; Risk; Simulation

Introduction

The main mechanism for the rare and costly widespread blackouts of bulk power transmission systems is cascading failure. Cascading failure can be defined as a sequence of dependent events that successively weaken the power system (IEEE PES CAMS Task Force on Cascading Failure 2008). The events and their dependencies are very varied and include outages or failures of many different parts of the power system and a whole range of possible physical, cyber, and human interactions. The events and dependencies tend to be rare or complicated, since the common and straightforward failures tend to be already mitigated by engineering design or operating practice.

Examples of a small initial outage cascading into a complicated sequence of dependent outages are the August 10, 1996, blackout of the Northwest United States that disconnected power to about 7.5 million customers (Kosterev et al. 1999) and the August 14, 2003 blackout of about 50 million customers in Northeastern United States and Canada (US-Canada Power System Outage Task Force 2004). Although such extreme events are rare, the direct costs run to billions of dollars and the disruption to society is substantial. Large blackouts also have a strong effect on shaping the way power systems are regulated and the reputation of the power industry. Moreover, some blackouts involve social disruptions that can multiply the economic damage. The hardship to people and possible deaths underscore the engineer's responsibility to work to avoid blackouts.

It is useful when analyzing cascading failure to consider cascading events of all sizes, including the short cascades that do not lead to interruption

of power to customers and cascades that involve events in other infrastructures, especially since loss of electricity can significantly impair other essential or economically important infrastructures. Note that in the context of interacting infrastructures, the term "cascading failure" sometimes has the more restrictive definition of events cascading *between* infrastructures (Rinaldi et al. 2001).

Blackout Risk

Cascading failure is a sequence of dependent events that successively weaken the power system. At a given stage in the cascade, the previous events have weakened the power system so that further events are more likely. It is this dependence that makes the long series of cascading events that cause large blackouts likely enough to pose a substantial risk. (If the events were independent, then the probability of a large number of events would be the product of the small probabilities of individual events and would be vanishingly small.) The statistics for the distribution of sizes of blackouts have correspondingly "heavy tails" indicating that blackouts of all sizes, including large blackouts, can occur. Large blackouts are rare, but they are expected to happen occasionally, and they are not "perfect storms."

In particular, it has been observed in several developed countries that the probability distribution of blackout size has an approximate power law dependence (Carreras et al. 2004b; Dobson et al. 2007; Hines et al. 2009). (The power law is of course limited in extent because every grid has a largest possible blackout in which the entire grid blacks out.) The power law region can be explained using ideas from complex systems theory. The main idea is that over the long term, the power grid reliability is shaped by the engineering responses to blackouts and the slow load growth and tends to evolve towards the power law distribution of blackout size (Dobson et al. 2007; Ren et al. 2008).

Blackout risk can be defined as the product of blackout probability and blackout cost. One simple assumption is that blackout cost is roughly proportional to blackout size, although larger blackouts may well have costs (especially indirect costs) that increase faster than linearly. In the case of the power law dependence, the larger blackouts can become rarer at a similar rate as costs increase, and then the risk of large blackouts is comparable to or even exceeding the risk of small blackouts. Mitigation of blackout risk should consider both small and large blackouts, because mitigating the small blackouts that are easiest to analyze may inadvertently increase the risk of large blackouts (Newman et al. 2011).

Approaches to quantify blackout risk are challenging and emerging, but there are also valuable approaches to mitigating blackout risk that do not quantify the blackout risk. The n-1 criterion that requires the power system to survive any single component failure has the effect of reducing cascading failures. The individual mechanisms of dependence in cascades (overloads, protection failures, voltage collapse, transient stability, lack of situational awareness, human error, etc.) can be addressed individually by specialized analyses or simulations or by training and procedures. Credible initiating outages can be sampled and simulated, and those resulting in cascading can be mitigated (Hardiman et al. 2004). This can be thought of as a "defense in depth" approach in which mitigating a subset of credible contingencies is likely to mitigate other possible contingencies not studied. Moreover, when blackouts occur, a postmortem analysis of that particular sequence of events leads to lessons learned that can be implemented to mitigate the risk of some similar blackouts (US-Canada Power System Outage Task Force 2004).

Simulation and Models

There are many simulations of cascading blackouts using Monte Carlo and other methods, for example, Hardiman et al. (2004), Carreras et al. (2004a), Chen et al. (2005), Kirschen et al. (2004), Anghel et al. (2007), and Bienstock and Mattia (2007). All these simulations select and approximate a modest subset of the many physical and engineering mechanisms of

cascading failure, such as line overloads, voltage collapse, and protection failures. In addition, operator actions or the effects of engineering the network may also be crudely represented. Some of the simulations give a set of credible cascades, and others approximately estimate blackout risk.

Except for describing the initial outages, where there is a wealth of useful knowledge, much of standard risk analysis and modeling does not easily apply to cascading failure in power systems because of the variety of dependencies and mechanisms, the combinatorial explosion of rare possibilities, and the heavy-tailed probability distributions. However, progress has been made in probabilistic models of cascading (Chen et al. 2006; Dobson 2012; Rahnamay-Naeini et al. 2012).

The goal of high-level probabilistic models is to capture salient features of the cascade without detailed models of the interactions and dependencies. They provide insight into cascading failure data and simulations, and parameters of the high-level models can serve as metrics of cascading.

Branching process models are transient Markov probabilistic models in which, after some initial outages, the outages are produced in successive generations. Each outage in each generation (a "parent" outage) produces a probabilistic number of outages ("children" outages) in the next generation according to an offspring probability distribution. The children failures then become parents to produce the next generation and so on, until there is a generation with zero children and the cascade stops. As might be expected, a key parameter describing the cascading is its average propagation, which is the average number of children outages per parent outage. Branching processes have traditionally been applied to many cascading processes outside of risk analysis (Harris), but they have recently been validated and applied to estimate the distribution of the total number of outages from utility outage data (Dobson 2012). A probabilistic model that tracks the cascade as it progresses in time through lumped grid states is presented in Rahnamay-Naeini et al. (2012).

There is an extensive complex networks literature on cascading in abstract networks that is largely motivated by idealized models of propagation of failures in the Internet. The way that failures propagate only along the network links is not realistic for power systems, which satisfy Kirchhoff's laws so that many types of failures propagate differently. For example, line overloads tend to propagate along cutsets of the network. However, the high-level qualitative results of phase transitions in the complex networks have provided inspiration for similar effects to be discovered in power system models (Dobson et al. 2007). There is also a possible research opportunity to elaborate the complex network models to incorporate some of the realities of power system and then validate them.

Summary and Future Directions

One challenge for simulation is what selection of phenomena to model and in how much detail in order to get useful engineering results. Faster simulations would help to ease the requirements of sampling appropriately from all the sources of uncertainty. Better metrics of cascading in addition to average propagation need to be developed and extracted from real and simulated data in order to better quantify and understand blackout risk. There are many new ideas emerging to analyze and simulate cascading failure, and the next step is to validate and improve these new approaches by comparing them with observed blackout data. Overall, there is an exciting challenge to build on the more deterministic approaches to mitigate cascading failure and find ways to more directly quantify and mitigate cascading blackout risk by coordinated analysis of real data, simulation, and probabilistic models.

Cash Management

Abel Cadenillas
University of Alberta, Edmonton, AB, Canada

Abstract

Cash on hand (or cash held in highly liquid form in a bank account) is needed for routine business and personal transactions. The problem of determining the right amount of cash to hold involves balancing liquidity against investment opportunity costs. This entry traces solutions using both discrete-time and continuous-time stochastic models.

Keywords

Brownian motion; Inventory theory; Stochastic impulse control

Definition

A firm needs to keep cash, either in the form of cash on hand or as a bank deposit, to meet its daily transaction requirements. Daily inflows

and outflows of cash are random. There is a finite target for the cash balance, which could be zero in some cases. The firm wants to select a policy that minimizes the expected total discounted cost for being far away from the target during some time horizon. This time horizon is usually infinity. The firm has an incentive to keep the cash level low, because each unit of positive cash leads to a holding cost since cash has alternative uses like dividends or investments in earning assets. The firm has an incentive to keep the cash level high, because penalty costs are generated as a result of delays in meeting demands for cash. The firm can increase its cash balance by raising new capital or by selling some earnings assets, and it can reduce its cash balance by paying dividends or investing in earning assets. This control of the cash balance generates fixed and proportional transaction costs. Thus, there is a cost when the cash balance is different from its target, and there is also a cost for increasing or reducing the cash reserve. The objective of the manager is to minimize the expected total discounted cost.

Hasbrouck (2007), Madhavan and Smidt (1993), and Manaster and Mann (1996) study inventories of stocks that are similar to the cash management problem.

The Solution

The qualitative form of optimal policies of the cash management problem in discrete time was studied by Eppen and Fama (1968, 1969), Girgis (1968), and Neave (1970). However, their solutions were incomplete.

Many of the difficulties that they and other researchers encountered in a discrete-time framework disappeared when it was assumed that decisions were made continuously in time and that demand is generated by a Brownian motion with drift. Vial (1972) formulated the cash management problem in continuous time with fixed and proportional transaction costs, linear holding and penalty costs, and demand for cash generated by a Brownian motion with drift. Under very

strong assumptions, Vial (1972) proved that if an optimal policy exists, then it is of a simple form (a, α, β, b).

This means that the cash balance should be increased to level α when it reaches level a and should be reduced to level β when it reaches level b. Constantinides (1976) assumed that an optimal policy exists and it is of a simple form, and determined the above levels and discussed the properties of the optimal solution. Constantinides and Richard (1978) proved the main assumptions of Vial (1972) and therefore obtained rigorously a solution for the cash management problem.

Constantinides and Richard (1978) applied the theory of stochastic impulse control developed by Bensoussan and Lions (1973, 1975, 1982). He used a Brownian motion W to model the uncertainty in the inventory. Formally, he considered a probability space $(\Omega, \mathcal{F}, P)$ together with a filtration $(\mathcal{F}_t)$ generated by a one-dimensional Brownian motion W. He considered $X_t :=$ inventory level at time t, and assumed that X is an adapted stochastic process given by

$$X_t = x - \int_0^t \mu \, ds - \int_0^t \sigma \, dW_s + \sum_{i=1}^{\infty} I_{\{\tau_i < t\}} \xi_i.$$

Here, $\mu > 0$ is the drift of the demand and $\sigma > 0$ is the volatility of the demand. Furthermore, τ_i is the time of the i-th intervention and ξ_i is the intensity of the i-th intervention.

A stochastic impulse control is a pair

$$((\tau_n); (\xi_n))$$
$$= (\tau_0, \tau_1, \tau_2, \ldots, \tau_n, \ldots; \xi_0, \xi_1, \xi_2, \ldots, \xi_n, \ldots),$$

where

$$\tau_0 = 0 < \tau_1 < \tau_2 < \cdots < \tau_n < \cdots$$

is an increasing sequence of stopping times and (ξ_n) is a sequence of random variables such that each $\xi_n : \Omega \mapsto \mathbf{R}$ is measurable with respect

to $\mathcal{F}_{\tau_n}$. We assume $\xi_0 = 0$. The management (the controller) decides to act at time

$$X_{\tau_i^+} = X_{\tau_i} + \xi_i.$$

We note that ξ_i and X can also take negative values. The management wants to select the pair

$$((\tau_n); (\xi_n))$$

that minimizes the functional J defined by

$$J(x; ((\tau_n); (\xi_n))) := E\left[\int_0^\infty e^{-\lambda t} f(X_t)dt \right.$$
$$\left. + \sum_{n=1}^\infty e^{-\lambda \tau_n} g(\xi_n) I_{\{\tau_n < \infty\}}\right],$$

where

$$f(x) = \max(hx, -px)$$

and

$$g(\xi) = \begin{cases} C + c\xi & \text{if } \xi > 0 \\ \min(C, D) & \text{if } \xi = 0 \\ D - d\xi & \text{if } \xi < 0 \end{cases}$$

Furthermore, $\lambda > 0, C, c, D, d \in (0, \infty)$, and $h, p \in (0, \infty)$. Here, f represents the running cost incurred by deviating from the aimed cash level 0, C represents the fixed cost per intervention when the management pushes the cash level upwards, D represents the fixed cost per intervention when the management pushes the cash level downwards, c represents the proportional cost per intervention when the management pushes the cash level upwards, d represents the proportional cost per intervention when the management pushes the cash level downwards, and λ is the discount rate.

Classical Frequency-Domain Design Methods

J. David Powell and Abbas Emami-Naeini
Stanford University, Stanford, CA, USA

Abstract

The design of feedback control systems in industry is probably accomplished using frequency-response (FR) methods more often than any other. Frequency-response design is popular primarily because it provides good designs in the face of uncertainty in the plant model ($G(s)$ in Fig. 1). For example, for systems with poorly known or changing high-frequency resonances, we can temper the feedback design to alleviate the effects of those uncertainties. Currently, this tempering is carried out more easily using FR design than with any other method. The method is most effective for systems that are stable in open loop; however, it can also be applied to systems with instabilities. This section will introduce the reader to methods of design (i.e., finding $D(s)$ in Fig. 1) using lead and lag compensation. It will also cover the use of FR design to reduce steady-state errors and to improve robustness to uncertainties in high-frequency dynamics.

Keywords

Amplitude stabilization; Bandwidth; Bode plot; Crossover frequency; Frequency response; Gain; Gain stabilization; Gain margin; Notch filter; Phase; Phase margin; Stability

Introduction

Finding an appropriate compensation ($D(s)$ in Fig. 1) using frequency response is probably the easiest of all feedback control design methods. Designs are achievable starting with the FR plots of both magnitude and phase of $G(s)$ then selecting $D(s)$ to achieve certain values of the

gain and/or phase margins and system bandwidth or error characteristics. This section will cover the design process for finding an appropriate $D(s)$.

Design Specifications

As discussed in Section X, the **gain margin (GM)** is the factor by which the gain can be raised before instability results. The **phase margin (PM)** is the amount by which the phase of $D(j\omega)G(j\omega)$ exceeds $-180°$ when $|D(j\omega)G(j\omega)| = 1$, the **crossover frequency**. Performance requirements for control systems are often partially specified in terms of PM and/or GM. For example, a typical specification might include the requirement that PM > 50° and GM > 5. It can be shown that the PM tends to correlate well with the damping ratio, ζ, of the closed-loop roots. In fact, it is shown in Franklin et al. (2010), that

$$\zeta \cong \frac{\text{PM}}{100}$$

for many systems; however, the actual resulting damping and/or response overshoot of the final closed-loop system will need to be verified if they are specified as well as the PM. A PM of 50° would tend to yield a ζ of 0.5 for the closed-loop roots, which is a modestly damped system. The GM does not generally correlate directly with the damping ratio, but is a measure of the degree of stability and is a useful secondary specification to ensure stability.

Another design specification is the **bandwidth**, which was defined in Section X. The bandwidth is a direct measure of the frequency at which the closed-loop system starts to fail in following the input command. It is also a measure of the speed of response of a closed-loop system. Generally speaking, it correlates well with the step response rise time of the system.

In some cases, the **steady-state error** must be less than a certain amount. As discussed in Franklin et al. (2010), the steady-state error is a direct function of the low-frequency gain of
Classical Frequency-Domain Design Methods, Fig. 1 Feedback system showing compensation, $D(s)$ (Source: Franklin et al. (2010, p-249), Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

the FR magnitude plot. However, increasing the low-frequency gain typically will raise the entire magnitude plot upward, thus increasing the magnitude 1 crossover frequency and, therefore, increasing the speed of response and bandwidth of the system.

Compensation Design

In some cases, the design of a feedback compensation can be accomplished by using proportional control only, i.e., setting $D(s) = K$ (see Fig. 1) and selecting a suitable value for K. This can be accomplished by plotting the magnitude and phase of $G(s)$, looking at $|G(j\omega)|$ at the frequency where $\angle G(j\omega) = -180°$, and then selecting K so that $|KG(j\omega)|$ yields the desired GM. Similarly, if a particular value of PM is desired, one can find the frequency where $\angle G(j\omega) = -180° +$ the desired PM. The value of $|KG(j\omega)|$ at that frequency must equal 1; therefore, the value of $|G(j\omega)|$ must equal $1/K$. Note that the $|KG(j\omega)|$ curve moves vertically based on the value of K; however the $\angle KG(j\omega)$ curve is not affected by the value of K. This characteristic simplifies the design process.

In more typical cases, proportional feedback alone is not sufficient. There is a need for a certain damping (i.e., PM) and/or speed of response (i.e., bandwidth) and there is no value of K that will meet the specifications. Therefore, some increased damping from the compensation is required. Likewise, a certain steady-state error requirement and its resulting low-frequency gain will cause the $|D(j\omega)G(j\omega)|$ to be greater than desired for an acceptable PM, so more phase lead is required from the compensation. This is

typically accomplished by **lead compensation**. A phase increase (or lead) is accomplished by placing a zero in $D(s)$. However, that alone would cause an undesirable high-frequency gain which would amplify noise; therefore, a first-order pole is added in the denominator at frequencies substantially higher than the zero break point of the compensator. Thus, the phase lead still occurs, but the amplification at high frequencies is limited. The resulting lead compensation has a transfer function of
$$D(s) = K\frac{Ts + 1}{\alpha Ts + 1}, \qquad \alpha < 1, \qquad (1)$$

where $1/\alpha$ is the ratio between the pole/zero break-point frequencies. Figure 2 shows the frequency response of this lead compensation. The maximum amount of phase lead supplied is dependent on the ratio of the pole to zero and is shown in Fig. 3 as a function of that ratio.

For example, a lead compensator with a zero at $s = -2$ ($T = 0.5$) and a pole at $s = -10$ ($\alpha T = 0.1$) (and thus $\alpha = \frac{1}{5}$) would yield the maximum phase lead of $\phi_{max} = 40°$. Note from the figure that we could increase the phase lead almost up to $90°$ using higher values of the **lead ratio**, $1/\alpha$; however, Fig. 2 shows that increasing values of $1/\alpha$ also produces higher amplifications at higher frequencies. Thus, our task is to select a value of $1/\alpha$ that is a good compromise between an acceptable PM and acceptable noise sensitivity at high frequencies. Usually the compromise suggests that a lead compensation should contribute a maximum of $70°$ to the phase. If a greater phase lead is needed, then a double-lead compensation would be suggested, where

Classical Frequency-Domain Design Methods, Fig. 2 Lead-compensation frequency response with $1/\alpha = 10$, $K = 1$ (Source: Franklin et al. (2010, p-349), Reprinted by permission of Pearson Education, Inc.)

$$D(s) = K\left(\frac{Ts+1}{\alpha Ts+1}\right)^2.$$

Even if a system had negligible amounts of noise present, the pole must exist at some point because of the impossibility of building a pure differentiator. No physical system – mechanical or electrical or digital – responds with infinite amplitude at infinite frequencies, so there will be a limit in the frequency range (or bandwidth) for which derivative information (or phase lead) can be provided.

As an example of designing a lead compensator, let us design compensation for a DC motor with the transfer function

$$G(s) = \frac{1}{s(s+1)}.$$

We wish to obtain a steady-state error of less than 0.1 for a unit-ramp input and we desire a system bandwidth greater than 3 rad/sec. Furthermore, we desire a PM of 45°. To accomplish the error requirement, Franklin et al. shows that

$$e_{ss} = \lim_{s \to 0} s\left[\frac{1}{1 + D(s)G(s)}\right]R(s), \quad (2)$$

and if $R(s) = 1/s^2$ for a unit ramp, Eq. (2) reduces to

$$e_{ss} = \lim_{s \to 0}\left\{\frac{1}{s + D(s)[1/(s+1)]}\right\} = \frac{1}{D(0)}.$$

Therefore, we find that $D(0)$, the steady-state gain of the compensation, cannot be less than 10 if it is to meet the error criterion, so we pick $K = 10$. The frequency response of $KG(s)$ in Fig. 4 shows that the PM $= 20°$ if no phase lead is added by compensation. If it were possible to simply add phase without affecting the magnitude, we would need an additional phase of only 25° at the $KG(s)$ crossover frequency of $\omega = 3$ rad/sec. However, maintaining the same low-frequency gain and adding a compensator zero will increase the crossover frequency; hence, more than a 25° phase contribution will be required from the lead compensation. To be safe, we will design the lead compensator so that it supplies a maximum phase lead of 40°. Figure 3 shows that $1/\alpha = 5$ will accomplish that goal. We will derive the greatest benefit from the compensation if the maximum phase lead from the compensator occurs at the crossover frequency. With some trial and error, we determine

Classical Frequency-Domain Design Methods, Fig. 4 Frequency response for lead-compensation design (Source:
Franklin et al. (2010, p-352), Reprinted by permission of Pearson Education, Inc.)

that placing the zero at $\omega = 2$ rad/sec and the pole at $\omega = 10$ rad/sec causes the maximum phase lead to be at the crossover frequency. The compensation, therefore, is

$$D(s) = 10 \frac{s/2 + 1}{s/10 + 1}.$$

The frequency-response characteristics of $L(s) = D(s)G(s)$ in Fig. 4 can be seen to yield a PM of 53°, which satisfies the PM and steady-state error design goals. In addition, the crossover frequency of 5 rad/sec will also yield a bandwidth greater than 3 rad/sec, as desired.

Lag compensation is the same form as the lead compensation in Eq. (1) except that $\alpha > 1$. Therefore, the pole is at a lower frequency than the zero and it produces higher gain at lower frequencies. The compensation is used primarily to reduce steady-state errors by raising the low-frequency gain but without increasing the crossover frequency and speed of response. This can be accomplished by placing the pole and zero of the lag compensation well below the crossover frequency. Alternatively, lag compensation can also be used to improve the PM by keeping the low frequency gain the same, but reducing the gain near crossover, thus reducing the crossover frequency. That will usually improve the PM since the phase of the uncompensated system typically is higher at lower frequencies.

Systems being controlled often have high-frequency dynamic phenomena, such as mechanical resonances, that could have an impact on the stability of a system. In very-high-performance designs, these high-frequency dynamics are included in the plant model, and a compensator is designed with a specific knowledge of those dynamics. However, a more **robust** approach for designing with uncertain high-frequency dynamics is to keep the high-frequency gain low, just as we did for sensor-noise reduction. The reason for this can be seen from the gain–frequency relationship of a typical system, shown in Fig. 5. The only way instability can result from high-frequency dynamics is if an unknown high-frequency resonance causes the magnitude to rise above 1.

Classical Frequency-Domain Design Methods, Fig. 5 Effect of high-frequency plant uncertainty (Source: Franklin et al. (2010, p-372), Reprinted by permission of Pearson Education, Inc.)

Conversely, if all unknown high-frequency phenomena are guaranteed to remain below a magnitude of 1, stability can be guaranteed. The likelihood of an unknown resonance in the plant G rising above 1 can be reduced if the nominal high-frequency loop gain (L) is lowered by the addition of extra poles in $D(s)$. When the stability of a system with resonances is assured by tailoring the high-frequency magnitude never to exceed 1, we refer to this process as **amplitude** or **gain stabilization**. Of course, if the resonance characteristics are known exactly and remain the same under all conditions, a specially tailored compensation, such as a **notch filter** at the resonant frequency, can be used to tailor the phase for stability even though the amplitude does exceed magnitude 1 as explained in Franklin et al. (2010). Design of a notch filter is more easily carried out using **root locus** or **state-space** design methods, all of which are discussed in Franklin et al. (2010). This method of stabilization is referred to as **phase stabilization**. A drawback to phase stabilization is that the resonance information is often not available with adequate precision or varies with time; therefore, the method is more susceptible to errors in the plant model used in the design. Thus, we see that sensitivity to plant uncertainty

and sensor noise are both reduced by sufficiently low gain at high-frequency.

Summary and Future Directions

Before the common use of computers in design, frequency-response design was the only widely used method. While it is still the most widely used method for routine designs, complex systems and their design are being carried out using a multitude of methods. This section introduces just one of many possible methods.

Computational Complexity Issues in Robust Control

Onur Toker
Fatih University, Istanbul, Turkey

Abstract

Robust control theory has introduced several new and challenging problems for researchers. Some of these problems have been solved by innovative approaches and led to the development of new and efficient algorithms. However, some of the other problems in robust control theory had attracted significant amount of research, but none of the proposed algorithms were efficient, namely, had execution time bounded by a polynomial of the "problem size." Several important problems in robust control theory are either of decision type or of computation/approximation type, and one would like to have an algorithm which can be used to answer all or most of the possible cases and can be executed on a classical computer in reasonable amount of time. There is a branch of theoretical computer science, called theory of computation, which can be used to study the difficulty of problems in robust control theory. In the following, classical computer system, algorithm, efficient algorithm, unsolvability, tractability, *NP*-hardness, and *NP*-completeness will be introduced in a more rigorous fashion, with applications to problems from robust control theory.

Keywords

Approximation complexity; Computational complexity; *NP*-complete; *NP*-hard; Unsolvability

Introduction

The term algorithm is used to refer to **different** notions which are all somewhat consistent with our intuitive understanding. This ambiguity may sometimes generate significant confusion, and therefore, a rigorous definition is of extreme importance. One commonly accepted "intuitive" definition is a set of rules that a person can perform with paper and pencil. However, there are "algorithms" which involve random number generation, for example, finding a primitive root in $\mathbb{Z}_p$ (Knuth 1997). Based on this observation, one may ask whether a random number generation-based set of rules should be also considered as an algorithm, provided that it will terminate after finitely many steps for all instances of the

problem or for a significant majority of the cases. In a similar fashion, one may ask whether any real number, including irrational ones which cannot be represented on a digital computer without an approximation error, should be allowed as an input to an algorithm and, furthermore, should all calculations be limited to algebraic functions only or should exact calculation of non-algebraic functions, e.g., trigonometric functions, the gamma function, etc., be acceptable in an algorithm. Although all of these seem acceptable with respect to our intuitive understanding of the algorithm, from a rigorous point of view, they are different notions. In the context of robust control theory, as well as many other engineering disciplines, there is a separate and widely accepted definition of algorithm, which is based on today's digital computers, more precisely the Turing machine (Turing 1936). Alan M. Turing defined a "hypothetical computation machine" to formally define the notions of algorithm and computability. A Turing machine is, in principle, quite similar to today's digital computers widely used in many engineering applications. The engineering community seems to widely accept the use of current digital computers and Turing's definitions of algorithm and computability.

However, depending on new scientific, engineering, and technological developments, superior computation machines may be constructed. For example, there is no guarantee that quantum computing research will not lead to superior computation machines (Chen et al. 2006; Kaye et al. 2007). In the future, the engineering community may feel the need to revise formal definitions of algorithm, computability, tractability, etc., if such superior computation machines can be constructed and used for scientific/engineering applications.

Turing Machines and Unsolvability
Turing machine is basically a mathematical model of a simplified computation device. The original definition involves a tape-like device for memory. For an easy-to-read introduction to the Turing machine model, see Garey and Johnson (1979) and Papadimitriou (1995), and for more details, see Hopcroft et al. (2001),

Lewis and Papadimitriou (1998), and Sipser (2006). Despite this being a quite simple and low-performance "hardware" compared to today's engineering standards, the following two observations justify their use in the study of computational complexity of engineering problems. Anything which can be solved on today's current digital computers can be solved on a Turing machine. Furthermore, a polynomial-time algorithm on today's digital computers will correspond to again a polynomial-time algorithm on the original Turing machine, and vice versa. A widely accepted definition for an algorithm is a Turing machine with a program, which is guaranteed to terminate after finitely many steps.

For some mathematical and engineering problems, it can be shown that there can be no algorithm which can handle all possible cases. Such problems are called unsolvable. The condition "all cases" may be considered too tough, and one may argue that such negative results have only theoretical importance and have no practical implications. But such results do imply that we should concentrate our efforts on alternative research directions, like the development of algorithms only for cases which appear more frequently in real scientific/engineering applications, without asking the algorithm to work for the remaining cases as well.

Here is a famous unsolvable mathematical problem: Hilbert's tenth problem is basically the development of an algorithm for testing whether a Diophantine equation has an integer solution. However, in 1970, Matijasevich showed that there can be no such algorithm (Matiyasevich 1993). Therefore, we say that the problem of checking whether a Diophantine equation has an integer solution is unsolvable.

Several unsolvability results for dynamical systems can be proved by using the Post correspondence problem (Davis 1985) and the embedding of free semigroups into matrices. For example, the problem of checking the stability of saturated linear dynamical systems is proved to be undecidable (Blondel et al. 2001), meaning that no general stability test algorithm can be developed for such systems. A similar unsolvability result is reported in Blondel and

Tsitsiklis (2000a) for boundedness of switching systems of the type

$$x(k + 1) = A_{f(k)}x(k),$$

where f is assumed to be an arbitrary and unknown function from $\mathbb{N}$ into $\{0, 1\}$. A closely related asymptotic stability problem is equivalent to testing whether the joint spectral radius (JSR) (Rota and Strang 1960) of a set of matrices is less than one. For a quite long period of time, there was a conjecture called the finiteness conjecture (FC) (Lagarias and Wang 1995), which was generally believed or hoped to be true, at least for a group of researchers. FC may be interpreted as "For asymptotic stability of $x(k + 1) = A_{f(k)}x(k)$ type switching systems, it is enough to consider periodic switchings only." There was no known counterexample, and the truth of this conjecture would imply existence of an algorithm for the abovementioned JSR problem. However, it was shown in Bousch and Mairesse (2002) that FC is not true (see Blondel et al. (2003) for a simplified proof). There are numerous known computationally very valuable procedures related to JSR approximation, for example, see Blondel and Nesterov (2005) and references therein. However, the development of an algorithm to test whether JSR is less than one remains as an open problem.

For further results on unsolvability and unsolved problems in robust control, see Blondel et al. (1999), Blondel and Megretski (2004), and references therein.

Tractability, *NP*-Hardness, and *NP*-Completeness

The engineering community is interested in not only solution algorithms but algorithms which are fast even in the worst case and if not on the average. Sometimes, this speed requirement may be relaxed to being fast for most of the cases and sometimes to only a significant percentage of the cases. Currently, the theory of computation is developed around the idea of algorithms which are polynomial time even in the worst case, namely, execution time bounded by a polynomial of the problem size (Garey and Johnson 1979;

Papadimitriou 1995). Such algorithms are also called efficient, and associated problems are classified as tractable. The term problem size means number of bits used in a suitable encoding of the problem (Garey and Johnson 1979; Papadimitriou 1995).

One may argue that this worst-case approach of being always polynomial time is a quite conservative requirement. In reality, a practicing engineer may consider being polynomial time on the average quite satisfactory for many applications. The same may be true for algorithms which are polynomial time for most of the cases. However, the existing computational complexity theory is developed around this idea of being polynomial time even in the worst case. Therefore, many of the computational complexity results proved in the literature do not imply the impossibility of algorithms which are neither polynomial time on the average nor polynomial time for most of the cases. Note that despite not being efficient, such algorithms may be considered quite valuable by a practicing engineer. Tractability and efficiency can be defined in several different ways, but the abovementioned polynomial-time solvability even in the worst-case approach is widely adopted by the engineering community.

NP-hardness and *NP*-completeness are originally defined to express the inherent difficulty of decision-type problems, not for approximation-type problems. Although approximation complexity is an important and active research area in the theory of computation (Papadimitriou 1995), most of the classical results are on decision-type problems. Many robust control-related problems can be formulated as "Check whether $\gamma < 1$," which is a decision-type problem. Approximate value of γ may not be always good enough to "solve" the problem, i.e., to decide about robust stability. For certain other engineering applications for which approximate values of optimization problems are good enough to "solve" the problem, the complexity of a decision problem may not be very relevant. For example, in a minimum effort control problem, usually there may be no point in computing the exact value of the minimum, because good approximations will

be just fine for most cases. However, for a robust control problem, a result like $\gamma = 0.99 \pm 0.02$ may be not enough to decide about robust stability, although the approximation error is about 2 % only. Basically, both the conservativeness of the current tractability definition and the differences between decision- and approximation-type problems should be always kept in mind when interpreting computational complexity results reported here as well as in the literature.

In this subsection, and in the next one, we will consider decision problems only. The class P corresponds to decision problems which can be solved by a Turing machine with a suitable program in polynomial time (Garey and Johnson 1979). This is interpreted as decision problems which have polynomial-time solution algorithms. The definition of the class NP is more technical and involves nondeterministic Turing machines (Garey and Johnson 1979). It may be interpreted as the class of decision problems for which the truth of the problem can be verified in polynomial time. It is currently unknown whether P and NP are equal or not. This is a major open problem, and the importance of it in the theory of computation is comparable to the importance of Riemann hypothesis in number theory.

A problem is NP-complete if it is NP and every NP problem polynomially reduces to it (Garey and Johnson 1979). For an NP-complete problem, being in P is equivalent to $P = NP$. There are literally hundreds of such problems, and it is generally argued that since after several years of research nobody was able to develop a polynomial-time algorithm for these NP-complete problems, there is probably no such algorithm, and most likely $P \neq NP$. Although current evidence is more toward $P \neq NP$, this does not constitute a formal proof, and the history of mathematics and science is full of surprising discoveries.

A problem (not necessarily NP) is called NP-hard if and only if there is an NP-complete problem which is polynomial time reducible to it (Garey and Johnson 1979). Being NP-hard is sometimes called being intractable and means that unless $P = NP$, which is considered to be very unlikely by a group of researchers, no

polynomial-time solution algorithm can be developed. All NP-complete problems are also NP-hard, but they are only as "hard" as any other problem in the set of NP-complete problems.

The first known NP-complete problem is SATISFIABILITY (Cook 1971). In this problem, there is a single Boolean equation with several variables, and we would like to test whether there is an assignment to these variables which make the Boolean expression true. This important discovery enabled proofs of NP-completeness or NP-hardness of several other problems by using simple polynomial reduction techniques only (Garey and Johnson 1979). Among these, quadratic programming is an important one and led to the discovery of several other complexity results in robust control theory. The quadratic programming (QP) can be defined as

$$q = \min_{Ax \le b} x^T Q x + c^T x,$$

more precisely testing whether $q < 1$ or not (decision version). When the matrix Q is positive definite, convex optimization techniques can be used; however, the general version of the problem is NP-hard.

A related problem is linear programming (LP)

$$q = \min_{Ax \le b} c^T x,$$

which is used in certain robust control problems (Dahleh and Diaz-Bobillo 1994) and has a quite interesting status. Simplex method (Dantzig 1963) is a very popular computational technique for LP and is known to have polynomial-time complexity on the "average" (Smale 1983). However, there are examples where the simplex method requires exponentially growing number of steps with the problem size (Klee and Minty 1972). In 1979, Khachiyan proposed the ellipsoid algorithm for LP, which was the first known polynomial-time approximation algorithm (Schrijver 1998). Because of the nature of the problem, one can answer the decision version of LP in polynomial time by using the ellipsoid algorithm for approximation and stopping when the error is below a certain level.

But all of these results are for standard Turing machines with input parameters restricted to rational numbers. An interesting open problem is whether LP admits a polynomial algorithm in the real number model of computation.

Complexity of Certain Robust Control Problems

There are several computational complexity results for robust control problems (see Blondel and Tsitsiklis (2000b) for a more detailed survey). Here we summarize some of the key results on interval matrices and structured singular values.

Kharitonov theorem is about robust Hurwitz stability of polynomials with coefficients restricted to intervals (Kharitonov 1978). The problem is known to have a surprisingly simple solution; however, the matrix version of the problem has a quite different nature. If we have a matrix family

$$\mathcal{A} = \big\{ A \in \mathbb{R}^{n \times n} : \alpha_{i,j} \le A_{i,j} \le \beta_{i,j}, \\ i, j = 1, \ldots, n \big\}, \quad (1)$$

where $\alpha_{i,j}, \beta_{i,j}$ are given constants for $i, j = 1, \ldots, n$, then it is called an interval matrix. Such matrices do occur in descriptions of uncertain dynamical systems. The following two stability problems about interval matrices are known to be *NP*-hard:

Interval Matrix Problem 1 (IMP1): Decide whether a given interval matrix, $\mathcal{A}$, is robust Hur- witz stable or not. Namely, check whether all members of $\mathcal{A}$ are Hurwitz-stable matrices, i.e., all eigenvalues are in open left half plane.

Interval Matrix Problem 2 (IMP2): Decide whether a given interval matrix, $\mathcal{A}$, has a Hurwitz-stable matrix or not. Namely, check whether there exists at least one matrix in $\mathcal{A}$ which is Hurwitz stable.

For a proof of *NP*-hardness of IMP1, see Poljak and Rohn (1993) and Nemirovskii (1993), and for a proof of IMP2, see Blondel and Tsitsiklis (1997).

Another important problem is related to structured singular values (SSV) and linear fractional transformations (LFT), which are mainly used to study systems which have component-level uncertainties (Packard and Doyle 1993). Basically, bounds on the component-level uncertainties are given, and we would like to check whether the system is robustly stable or not. This is known to be *NP*-hard.

Structured Singular Value Problem (SSVP): Given a matrix M and uncertainty structure $\mathbf{\Delta}$, check whether the structured singular value $\mu_{\mathbf{\Delta}}(M) < 1$.

This is proved to be *NP*-hard for real, and mixed, uncertainty structures (Braatz et al. 1994), as well as for complex uncertainties with no repetitions (Toker and Ozbay 1996, 1998).

Approximation Complexity

Decision version of QP is *NP*-hard, but approximation of QP is quite "difficult" as well. An approximation is called a μ-approximation if the absolute value of the error is bounded by μ times the absolute value of max–min of the function. The following is a classical result on QP (Bellare and Rogaway 1995): Unless $P = NP$, QP does not admit a polynomial-time μ-approximation algorithm even for $\mu < 1/3$. This is sometimes informally stated as "QP is *NP*-hard to approximate." Much work is needed toward similar results on robustness margin and related optimization problems of the classical robust control theory.

An interesting case is the complex structured singular value computation with no repeated uncertainties. There is a convex relaxation of the problem, the standard upper bound $\overline{\mu}$, which is known to result in quite tight approximations for most cases of the original problem (Packard and Doyle 1993). However, despite strong numerical evidence, a formal proof of "good approximation for most cases" result is not available. We also do not have much theoretical information about how hard it is to approximate the complex structured singular value. For example, it is not known whether it admits a polynomial-time approximation algorithm with error bounded by, say, 5 %. In summary, much work needs to be done in these

directions for many other robust control problems whose decision versions are *NP*-hard.

Summary and Future Directions

The study of the "Is $P \neq NP$?" question turned out to be a quite difficult one. Researchers agree that really new and innovative tools are needed to study this problem. On one other extreme, one can question whether we can really say something about this problem within the Zermelo-Fraenkel (ZF) set theory or will it have a status similar to axiom of choice (AC) and the continuum hypothesis (CH) where we can neither refute nor provide a proof (Aaronson 1995). Therefore, the question may be indeed much deeper than we thought, and standard axioms of today's mathematics may not be enough to provide an answer. As for any such problem, we can still hope that in the future, new "self-evident" axioms may be discovered, and with the help of them, we may provide an answer.

All of the complexity results mentioned here are with respect to the standard Turing machine which is a simplified model of today's digital computers. Depending on the progress in science, engineering, and technology, if superior computation machines can be constructed, then some of the abovementioned problems can be solved much faster on these devices, and current results/problems of the theory of computation may no longer be of great importance or relevance for engineering and scientific applications. In such a case, one may also need to revise definitions of the terms algorithm, tractable, etc., according to these new devices.

Currently, there are several *NP*-hardness results about robust control problems, mostly *NP*-hardness of decision problems about robustness. However, much work is needed on the approximation complexity and conservatism of various convex relaxations of these problems. Even if a robust stability problem is *NP*-hard, a polynomial-time algorithm to estimate robustness margin with, say, 5 % error is not ruled out with the *NP*-hardness of the decision version of the problem. Indeed, a polynomial-time

and 5 % error-bounded result will be of great importance for practicing engineers. Therefore, such directions should also be studied, and various meaningful alternatives, like being polynomial time on the average or for most of cases or anything which makes sense for a practicing engineer, should be considered as an alternative direction.

In summary, computational complexity theory guides research on the development of algorithms, indicating which directions are dead ends and which directions are worth to investigate.

CACSD

Abstract

Computer-aided control system design (CACSD) encompasses a broad range of Methods and tools and technologies for system modelling, control system synthesis and tuning, dynamic system analysis and simulation, as well as validation and verification. The domain of CACSD enlarged progressively over decades from simple collections of algorithms and programs for control system analysis and synthesis to comprehensive tool sets and user-friendly environments supporting all aspects of developing and deploying advanced control systems in various application fields. This entry gives a brief introduction to CACSD and reviews

the evolution of key concepts and technologies underlying the CACSD domain. Several cornerstone achievements in developing reliable numerical algorithms; implementing robust numerical software; and developing sophisticated integrated modelling, simulation, and design environments are highlighted.

Keywords

CACSD; Modelling; Numerical analysis; Simulation; Software tools

Introduction

To design a control system for a plant, a typical *computer-aided control system design* (CACSD) work flow comprises several interlaced activities.

Model building is often a necessary first step consisting in developing suitable mathematical models to accurately describe the plant dynamical behavior. High-fidelity physical plant models obtained, for example, by using the first principles of modelling, primarily serve for analysis and validation purposes using appropriate simulation techniques. These dynamic models are usually defined by a set of *ordinary differential equations* (ODEs), *differential algebraic equation* (DAEs), or *partial differential equations* (PDEs). However, for control system synthesis purposes simpler models are required, which are derived by simplifying high-fidelity models (e.g., by linearization, discretization, or model reduction) or directly determined in a specific form from input-output measurement data using system identification techniques. Frequently used synthesis models are continuous or discrete-time *linear time-invariant* (LTI) models describing the nominal behavior of the plant in a specific operating point. The more accurate *linear parameter varying* (LPV) models may serve to account for uncertainties due to various performed approximations, nonlinearities, or varying model parameters.

Simulation of dynamical systems is a closely related activity to modelling and is concerned with performing virtual experiments on a given plant model to analyze and predict the dynamic behavior of a physical plant. Often, modelling and simulation are closely connected parts of dedicated environments, where specific classes of models can be built and appropriate simulation methods can be employed. Simulation is also a powerful tool for the validation of mathematical models and their approximations. In the context of CACSD, simulation is frequently used as a control system tuning-aid, as, for example, in an optimization-based tuning approach using time-domain performance criteria.

System analysis and synthesis are concerned with the investigation of properties of the underlying synthesis model and in the determination of a control system which fulfills basic requirements for the closed-loop controlled plant, such as stability or various time or frequency response requirements. The analysis also serves to check existence conditions for the solvability of synthesis problems, according to established design methodologies. An important synthesis goal is the guarantee of the performance robustness. To achieve this goal, robust control synthesis methodologies often employ optimization-based parameter tuning in conjunction with worst-case analysis techniques. A rich collection of reliable numerical algorithms are available to perform such analysis and synthesis tasks. These algorithms form the core of CACSD and their development represented one of the main motivations for CACSD-related research.

Performance robustness assessment of the resulting closed-loop control system is a key aspect of the verification and validation activity. For a reliable assessment, simulation-based worst-case analysis represents, often, the only way to prove the performance robustness of the synthesized control system in the presence of parametric uncertainties and variabilities.

Development of CACSD Tools

The development of CACSD tools for system analysis and synthesis started around 1960, immediately after general-purpose digital

computers, and new programming languages became available for research and development purposes. In what follows, we give a historical survey of these developments in the main CACSD areas.

Modelling and Simulation Tools

Among the first developments were modelling and simulation tools for continuous-time systems described by differential equations based on dedicated simulation languages. Over 40 continuous-system simulation languages had been developed as of 1974 (Nilsen and Karplus 1974), which evolved out of attempts at digitally emulating the behavior of widely used analog computers before 1960. A notable development in this period was the CSSL standard (Augustin et al. 1967), which defined a system as an interconnection of blocks corresponding to operators which emulated the main analog simulation blocks and implied the integration of the underlying ODEs using suitable numerical methods. For many years, the ACSL preprocessor to Fortran (Mitchel and Gauthier 1976) was one of the most successful implementations of the CSSL standard.

A turning point was the development of graphical user interfaces allowing graphical block diagram-based modelling. The most important developments were SystemBuild (Shah et al. 1985) and SIMULAB (later marketed as Simulink) (Grace 1991). Both products used a customizable set of block libraries and were seamlessly integrated in, respectively, MATRIXx and MATLAB, two powerful interactive matrix computation environments (see below). SystemBuild provided several advanced features such as event management, code generation, and DAE-based modelling and simulation. Simulink excelled from the beginning with its intuitive, easy-to-use user interface. Recent extensions of Simulink allow the modelling and simulation of hybrid systems, code generation for real-time applications, and various enhancements of the model building process (e.g., object-oriented modelling).

The object-oriented paradigm for system modelling was introduced with Dymola (Elmqvist 1978) to support physical system modelling based on interconnections of subsystems. The underlying modelling language served as the basis of the first version of Modelica (Elmquist et al. 1997), a modern equation-based modelling language which was the result of a coordinated effort for the unification and standardization of expertise gained over many years with object-oriented physical modelling. The latest developments in this area are comprehensive model libraries for different application domains such as mechanical, electrical, electronic, hydraulic, thermal, control, and electric power systems. Notable commercial front-ends for Modelica are Dymola, MapleSim, and SystemModeler, where the last two are tightly integrated in the symbolic computation environments Maple and Mathematica, respectively.

Numerical Software Tools

The computational tools for CACSD rely on many numerical algorithms whose development and implementation in computer codes was the primary motivation of this research area since its beginnings. The Automatic Synthesis Program (ASP) developed in 1966 (Kalman and Englar 1966) was implemented in FAP (Fortran Assembly Program) and ran only on an IBM 7090–7094 machine. The Fortran II version of ASP (known as FASP) can be considered to be the first collection of computational CACSD tools ported to several mainframe computers. Interestingly, the linear algebra computations were covered by only three routines (diagonal decomposition, inversion, and pseudoinverse), and no routines were used for eigenvalue or polynomial roots computation. The main analysis and synthesis functions covered the sampled-data discretization (via matrix exponential), minimal realization, time-varying Riccati equation solution for quadratic control, filtering, and stability analysis. The FASP itself performed the required computational sequences by interpreting simple commands with parameters. The extensive documentation containing a detailed description of algorithmic approaches and many examples marked the starting point of an intensive research on algorithms and numerical software, which culminated in the development of the

high-performance control and systems library SLICOT (Benner et al. 1999; Huffel et al. 2004). In what follows, we highlight the main achievements along this development process.

The direct successor of FASP is the Variable Dimension Automatic Synthesis Program (VASP) (implemented in Fortran IV on IBM 360) (White and Lee 1971), while a further development was ORACLS (Armstrong 1978), which included several routines from the newly developed eigenvalue package EISPACK (Garbow et al. 1977; Smith et al. 1976) as well as solvers for linear (Lyapunov, Sylvester) and quadratic (Riccati) matrix equations. From this point, the mainstream development of numerical algorithms for linear system analysis and synthesis closely followed the development of algorithms and software for numerical linear algebra. A common feature of all subsequent developments was the extensive use of robust linear algebra software with the Basic Linear Algebra Subprograms (BLAS) (Lawson et al. 1979) and the Linear Algebra Package (LINPACK) for solving linear systems (Dongarra et al. 1979). Several control libraries have been developed almost simultaneously, relying on the robust numerical linear algebra core software formed of BLAS, LINPACK, and EISPACK. Notable examples are RASP (based partly on VASP and ORACLS) (Grübel 1983) – developed originally by the University of Bochum and later by the German Aerospace Center (DLR); BIMAS (Varga and Sima 1985) and BIMASC (Varga and Davidoviciu 1986) – two Romanian initiatives; and SLICOT (Boom et al. 1991) – a Benelux initiative of several universities jointly with the Numerical Algorithm Group (NAG).

The last development phase was marked by the availability of the Linear Algebra Package (LAPACK) (Anderson et al. 1992), whose declared goal was to make the widely used EISPACK and LINPACK libraries run efficiently on shared memory vector and parallel processors. To minimize the development efforts, several active research teams from Europe started, in the framework of the NICONET project, a concentrated effort to develop a high-performance numerical software library

for CACSD as a new significantly extended version of the original SLICOT. The goals of the new library were to cover the main computational needs of CACSD, by relying exclusively on LAPACK and BLAS, and to guarantee similar numerical performance as that of the LAPACK routines. The software development used rigorous standards for implementation in Fortran 77, modularization, testing, and documentation (similar to that used in LAPACK). The development of the latest versions of RASP and SLICOT eliminated practically any duplication of efforts and led to a library which contained the best software from RASP, SLICOT, BIMAS, and BIMASC. The current version of SLICOT is fully maintained by the NICONET association (http://www.niconet-ev.info/en/) and serves as basis for implementing advanced computational functions for CACSD in interactive environments as MATLAB (http://www.mathworks.com), Maple (http://www.maplesoft.com/products/maple/), Scilab (http://www.scilab.org/) and Octave (http://www.gnu.org/software/octave/).

Interactive Tools

Early experiments during 1970–1985 included the development of several interactive CACSD tools employing menu-driven interaction, question-answer dialogues, or command languages. The April 1982 special issue of IEEE Control Systems Magazine was dedicated to CACSD environments and presented software summaries of 20 interactive CACSD packages. This development period was marked by the establishment of new standards for programming languages (Fortran 77, C), availability of high-quality numerical software libraries (BLAS, EISPACK, LINPACK, ODEPACK), transition from mainframe computers to minicomputers, and finally to the nowadays-ubiquitous personal computers as computing platforms, spectacular developments in graphical display technologies, and application of sound programming paradigms (e.g., strong data typing).

A remarkable event in this period was the development of MATLAB, a command language-based interactive matrix laboratory (Moler 1980).

The original version of MATLAB was written in Fortran 77. It was primarily intended as a student teaching tool and provided interactive access to selected subroutines from LINPACK and EISPACK. The tool circulated for a while in the public domain, and its high flexibility was soon recognized. Several CACSD-oriented commercial clones have been implemented in the C language, the most important among them being MATRIXx (Walker et al. 1982) and PC-MATLAB (Moler et al. 1985).

The period after 1985 until around 2000 can be seen as a consolidation and expansion period for many commercial and noncommercial tools. In an inventory of CACSD-related software issued by the Benelux Working Group on Software (WGS) under the auspices of the IEEE Control Systems Society, there were in 1992 in active development 70 stand-alone CACSD packages, 21 tools based on or similar to MATLAB, and 27 modelling/simulation environments. It is interesting to look more closely at the evolutions of the two main players MATRIXx and MATLAB, which took place under harshly competitive conditions.

MATRIXx with its main components Xmath, SystemBuild, and AutoCode had over many years a leading role (especially among industrial customers), excelling with a rich functionality in domains such as system identification, control system synthesis, model reduction, modelling, simulation, and code generation. After 2003, MATRIXx (http://www.ni.com/matrixx/) became a product of the National Instruments Corporation and complements its main product family LabView, a visual programming language-based system design platform and development environment (http://www.ni.com/labview).

MATLAB gained broad academic acceptance by integrating many new methodological developments in the control field into several control-related toolboxes. MATLAB also evolved as a powerful programming language, which allows easy object-oriented manipulation of different system descriptions via operator overloading. At present, the CACSD tools of MATLAB and Simulink represent the industrial and academic standard for CACSD. The existing CACSD tools are constantly extended and enriched with new model classes, new computational algorithms (e.g., structure-exploiting eigenvalue computations based on SLICOT), dedicated graphical user interfaces (e.g., tuning of PID controllers or control-related visualizations), advanced robust control system synthesis, etc. Also, many third-party toolboxes contribute to the wide usage of this tool.

Basic CACSD functionality incorporating symbolic processing techniques and higher precision computations is available in the Maple product MapleSim Control Design Toolbox as well as in the Mathematica Control Systems product. Free alternatives to MATLAB are the MATLAB-like environments Scilab, a French initiative pioneered by INRIA, and Octave, which has recently added some CACSD functionality.

Summary and Future Directions

The development and maintenance of integrated CACSD environments, which provide support for all aspects of the CACSD cycle such as modelling, design, and simulation, involve sustained, strongly interdisciplinary efforts. Therefore, the CACSD tool development activities must rely on the expertise of many professionals covering such diverse fields as control system engineering, programming languages and techniques, man-machine interaction, numerical methods in linear algebra and control, optimization, computer visualization, and model building techniques. This may explain why currently only a few of the commercial developments of prior years are still in use and actively maintained/developed. Unfortunately, the number of actively developed noncommercial alternative products is even lower. The dominance of MATLAB, as a de facto standard for both industrial and academic usage of integrated tools covering all aspects of the broader area of *computer-aided control engineering* (CACE), cannot be overseen.

The new trends in CACSD are partly related to handling more complex applications, involving time-varying (e.g., periodic, multi-rate sampled-data, and differential algebraic) linear dynamic systems, nonlinear systems with many parametric uncertainties, and large-scale models (e.g., originating from the discretization of PDEs). To address many computational aspects of model building (e.g., model reduction of large order systems), optimization-based robust controller tuning using multiple-model approaches, or optimization-based robustness assessment using global-optimization techniques, parallel computation techniques allow substantial savings in computational times and facilitate addressing computational problems for large-scale systems. A topic which needs further research is the exploitation of the benefits of combining numerical and symbolic computations (e.g., in model building and manipulation).

Recommended Reading

The historical development of CACSD concepts and techniques was the subject of several articles in reference works Rimvall and Jobling (1995) and Schmid (2002). A selection of papers on numerical algorithms underlying the development of CACSD appeared in Patel et al. (1994). The special issue No. 2/2004 of the IEEE Control Systems Magazine on *Numerical Awareness in Control* presents several surveys on different

aspects of developing numerical algorithms and software for CACSD.

The main trends over the last three decades in CACSD-related research can be followed in the programs/proceedings of the biannual IEEE Symposia on CACSD from 1981 to 2013 (partly available at http://ieeexplore.ieee.org) as well as of the triennial IFAC Symposia on CACSD from 1979 to 2000. Additional information can be found in several CACSD-focused survey articles and special issues (e.g., No. 4/1982; No. 2/2000) of the IEEE Control Systems Magazine.

Consensus of Complex Multi-agent Systems

Fabio Fagnani
Dipartimento di Scienze Matematiche 'G.L. Lagrange', Politecnico di Torino, Torino, Italy

Abstract

This entry provides a broad overview of the basic elements of consensus dynamics. It describes the classical Perron-Frobenius theorem that provides the main theoretical tool to study the convergence properties of such systems. Classes of consensus models that are treated include simple random walks on grid-like graphs and in graphs with a bottleneck, consensus on graphs with intermittently randomly appearing edges between nodes (gossip models), and models with nodes that do not modify their state over time (stubborn agent models). Application to cooperative control, sensor networks, and socioeconomic models are mentioned.

Keywords

Consensus; Electrical networks; Gossip model; Spectral gap; Stubborn agents

Multi-agent Systems and Consensus

Multi-agent systems constitute one of the fundamental paradigms of science and technology of the present century (Castellano et al. 2009; Strogatz 2003). The main idea is that of creating complex dynamical evolutions from the interactions of many simple units. Indeed such collective behaviors are quite evident in biological and social systems and were indeed considered in earlier times. More recently, the digital revolution and the miniaturization in electronics have made possible the creation of man-made complex architectures of interconnected simple devices (computers, sensors, cameras). Moreover, the creation of the Internet has opened a totally

new form of social and economic aggregation. This has strongly pushed towards a systematic and deep study of multi-agent dynamical systems. Mathematically they typically consist of a graph where each node possesses a state variable; states are coupled at the dynamical level through dependences determined by the edges in the graph. One of the challenging problems in the field of multi-agent systems is to analyze the emergence of complex collective phenomena from the interactions of the units which are typically quite simple. Complexity is typically the outcome of the topology and the nature of interconnections.

Consensus dynamics (also known as average dynamics) (Carli et al. 2008; Jadbabaie et al. 2003) is one of the most popular and simplest multi-agent dynamics. One convenient way to introduce it is with the language of social sciences. Imagine that a number of independent units possess an information represented by a real number, for instance, such number can represent an opinion on a given fact. Units interact and change their opinion by averaging with the opinions of other units. Under certain assumptions, this will lead the all community to converge to a consensus opinion which takes into consideration all the initial opinion of the agents. In social sciences, empiric evidences (Galton 1907) have shown how such aggregate opinion may give a very good estimation of unknown quantities: such phenomenon has been proposed in the literature as wisdom of crowds (Surowiecki 2004).

Consensus Dynamics, Graphs, and Stochastic Matrices

Mathematically, consensus dynamics are special linear dynamical systems of type

$$x(t+1) = Px(t) \qquad (1)$$

where $x(t) \in \mathbb{R}^\mathcal{V}$ and $P \in \mathbb{R}^{\mathcal{V} \times \mathcal{V}}$ is a *stochastic matrix* (e.g., a matrix with nonnegative elements such that every row sums to 1). $\mathcal{V}$ represents the finite set of units (agents) in the network and $x(t)_v$ is to be interpreted has the state (opinion) of agent v at time t. Equation (1) implies that states of agents at time $t+1$ are convex

combinations of the components of $x(t)$: this motivates the term averaging dynamics. Stochastic matrices owe their name to their use in probability: the term P_{vw} can be interpreted as the probability of making a jump in the graph from state v to state w. In this way you construct what is called a random walk on the graph $\mathcal{G}$.

The network structure is hidden in the nonzero pattern of P. Indeed we can associate to P a graph: $\mathcal{G}_P = (\mathcal{V}, \mathcal{E}_P)$ where the set of edges is given by $\mathcal{E}_P := \{(u, v) \in \mathcal{V} \times \mathcal{V} \mid P_{uv} > 0\}$. Elements in $\mathcal{E}_P$ represent the communication edges among the units: if $(u, v) \in \mathcal{E}_P$, it means that unit u has access to the state of unit v. Denote by $\mathbb{1} \in \mathbb{R}^\mathcal{V}$ the all 1's vector. Notice that $P\mathbb{1} = \mathbb{1}$: this shows that once the states of units are at consensus, they will no longer evolve. Will the dynamics always converge to a consensus point?

Remarkably, some of the key properties of P responsible for the transient and asymptotic behavior of the linear system (1) are determined by the connectivity properties of the underlying graph $\mathcal{G}_P$. We recall that, given two vertices $u, v \in \mathcal{V}$, a *path* (of length l) from u to v in $\mathcal{G}_P$ is any sequence of vertices $u = u_1, u_2, \ldots, u_{l+1} = v$ such that $(u_i, u_{i+1}) \in \mathcal{E}_P$ for every $i = 1, \ldots, s$. $\mathcal{G}_P$ is said to be *strongly connected* if for any pair of vertices $u \neq v$ in $\mathcal{V}$ there is a path in $\mathcal{G}_P$ connecting u to v. The *period* of a node u is defined as the greatest common divisor of the lengths of all closed paths from u to u. In the strongly connected graph, all nodes have the same period, and the graph is called aperiodic if such a period is 1. If x is a vector, we will use the notation x^* to denote its transpose. If A is a finite set, $|A|$ denotes the number of elements in A. The following classical result holds true (Gantmacher 1959):

Theorem 1 (Perron-Frobenius) *Assume that $P \in \mathbb{R}^{\mathcal{V} \times \mathcal{V}}$ is such that $\mathcal{G}_P$ is strongly connected and aperiodic. Then,*

1. *1 is an algebraically simple eigenvalue of P.*
2. *There exists a (unique) probability vector $\pi \in \mathbb{R}^\mathcal{V}$ ($\pi_v > 0$ for all v and $\sum_v \pi_v = 1$) which is a left eigenvector for P, namely, $\pi^* P = \pi^*$.*
3. *All the remaining eigenvalues of P are of modulus strictly less than 1.*

A straightforward linear algebra consequence of this result is that $P^t \to \mathbb{1}\pi^*$ for $t \to +\infty$. This yields

$$\lim_{t \to +\infty} x(t) = \lim_{t \to +\infty} P^t x(0) = \mathbb{1}(\pi^* x(0)) \tag{2}$$

All agents' state are thus converging to the common value $\pi^* x(0)$, called *consensus point* which is a convex combination of the initial states with weights given by the invariant probability components.

If π is the uniform vector (i.e., $\pi_v = |\mathcal{V}|^{-1}$ for all units v), the common asymptotic value is simply the arithmetic mean of the initial states: all agents equally contribute to the final common state. A special case when this happens is when P is symmetric. The distributed computation of the arithmetic mean is an important step to solve estimation problems for sensor networks. As a specific example, consider the situation where there are N sensors deployed in a certain area and each of them makes a noisy measurement of a physical quantity x. Let $y_v = x + \omega_v$ be the measure obtained by sensor v, where ω_v is a zero mean Gaussian noise. It is well known that if noises are independent and identically distributed, the optimal mean square estimator of the quantity x given the entire set of measurements $\{y_v\}$ is exactly given by $\hat{x} = N^{-1} \sum_v y_v$. Other fields of application is in the control of cooperative autonomous vehicles (Fax and Murray 2004; Jadbabaie et al. 2003).

Basic linear algebra allows to study the rate of convergence to consensus. Indeed, if $\mathcal{G}_P$ is strongly connected and aperiodic, the matrix P has all its eigenvalues in the unit ball: 1 is the only eigenvalue with modulo equal to 1, while all the others have modulo strictly less than one. If we denote by $\rho_2 < 1$ the largest modulo of such eigenvalues (different from 1), we can show that $x(t) - \mathbb{1}(\pi^* x(0))$ converges exponentially to 0 as ρ_2^t. In the following, we will briefly refer to ρ_2 as to the *second eigenvalue* of P.

Examples and Large-Scale Analysis

In this section, we present some classical examples. Consider a strongly connected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. The *adjacency matrix* of $\mathcal{G}$ is a square matrix $A_\mathcal{G} \in \{0,1\}^{\mathcal{V} \times \mathcal{V}}$ such that $(A_\mathcal{G})_{uv} = 1$ iff $(u,v) \in \mathcal{E}$. $\mathcal{G}$ is said to be symmetric if $A_\mathcal{G}$ is symmetric. Given a symmetric graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we can consider the stochastic matrix P given by $P_{uv} = d_u^{-1}(A_\mathcal{G})_{uv}$ where $d_u = \sum_v (A_\mathcal{G})_{uv}$ is the *degree* of node u. P is called the *simple random walk (SRW)* on $\mathcal{G}$: each agent gives the same weight to the state of its neighbors. Clearly, $\mathcal{G}_P = \mathcal{G}$. A simple check shows that $\pi_v = d_v/|\mathcal{E}|$ is the invariant probability for P. The consensus point is given by

$$\pi^* x(0) = |\mathcal{E}|^{-1} \sum_v d_v x(0)_v$$

Each node contributes with its initial state to this consensus with a weight which is proportional to the degree of the node. Notice that the SRW P is symmetric iff the graph is regular, namely, all units have the same degree.

We now present a number of classical examples based on families of graphs with larger and larger number of nodes N. In this setting, particularly relevant is to understand the behavior of the second eigenvalue ρ_2 as a function of N. Typically, one considers $\epsilon > 0$ fixed and solves the equation $\rho_2^t = \epsilon$. The solution $\tau = (\ln \rho_2^{-1})^{-1} \ln \epsilon^{-1}$ will be called the *convergence time*: it essentially represents the time needed to shrink of a factor ϵ the distance to consensus. Dependence of ρ_2 on N will also yield that τ will be a function of N. In the sequel, we will investigate such dependence for SRW's on certain classical families of graphs.

Example 1 (SRW on a complete graph) Consider the complete graph on the set $\mathcal{V}$: $K_\mathcal{V} := (\mathcal{V}, \mathcal{V} \times V)$ (also self loops are present). The SRW on $K_\mathcal{V}$ is simply given by $P = N^{-1}\mathbb{1}\mathbb{1}^*$ where $N = |\mathcal{V}|$. Clearly, $\pi = N^{-1}\mathbb{1}$. Eigenvalues of P are 1 with multiplicity 1 and 0 with multiplicity $N - 1$. Therefore, $\rho_2 = 0$. Consensus in this case

is achieved in just one step: $x(t) = N^{-1} \mathbb{1} \mathbb{1}^* x(0)$ for all $t \geq 1$.

Example 2 (SRW on a cycle graph) Consider the symmetric cycle graph $C_N = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{0, \ldots, N-1\}$ and $\mathcal{E} = \{(v, v+1), (v+1, v)\}$ where sum is mod N. The graph C_N is clearly strongly connected and is also aperiodic if N is odd. The corresponding SRW P has eigenvalues

$$\lambda_k = \cos \frac{2\pi k}{N}$$

Therefore, if N is odd, the second eigenvalue is given by

$$\rho_2 = \cos \frac{2\pi}{N} = 1 - 2\pi^2 \frac{1}{N^2} + o(N^{-2}) \qquad (3)$$
$$\text{for } N \to +\infty$$

while the corresponding convergence time is given by

$$\tau = (\ln \rho_2^{-1})^{-1} \ln \epsilon^{-1} \asymp N^2 \quad \text{for } N \to +\infty$$

Example 3 (SRW on toroidal grids) The toroidal d-grids C_n^d is formally obtained as a product of cycle graphs. The number of nodes is $N = n^d$. It can be shown that the convergence time behaves as

$$\tau \asymp N^{2/d} \quad \text{for } N \to +\infty$$

Convergence time exhibits a slower growth in N as the dimension d of the grid increases: this is intuitive since the increase in d determines a better connectivity of the graph and a consequently faster diffusion of information.

For a general stochastic matrix (even for SRW on general graphs), the computation of the second eigenvalue is not possible in closed form and can actually be also difficult from a numerical point of view. It is therefore important to develop tools for efficient estimation. One of these is based on the concept of bottleneck: if a graph can be splitted into two loosely connected parts, then consensus dynamics will necessarily exhibit a slow convergence.

Formally, given a symmetric graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and a subset of nodes $S \subseteq \mathcal{V}$, define e_S as the number of edges with at least one node in S and e_{SS} as the number of edges with both nodes in S. The bottleneck of S in G is defined as $\Phi(S) = e_{SS}/e_S$. Finally, the *bottleneck ratio* of $\mathcal{G}$ is defined as

$$\Phi_* := \min_{S : e_S/e \leq 1/2} \Phi(S)$$

where $e = |\mathcal{E}|$ is the number of edges in the graph.

Let P be the SRW on $\mathcal{G}$ and let ρ_2 be its second eigenvalue. Then,

Proposition 1 (Cheeger bound Levin et al. 2008)
$$1 - \rho_2 \leq 2\Phi_*. \qquad (4)$$

Example 4 (Graphs with a bottleneck) Consider two complete graphs with n nodes connected by just one edge. If S is the set of nodes of one of the two complete graphs, we obtain

$$\Phi(S) = \frac{1}{n^2 + 1}$$

Bound (4) implies that the convergence time is at least of the order of n^2 in spite of the fact that in each complete graph convergence would be in finite time!

Other Models

The systems studied so far are based on the assumptions that units all behave the same, and they share a common clock and update their state in a synchronous fashion. In this section, we discuss more general models.

Random Consensus Models
Regarding the assumption of synchronicity, it turns out to be unfeasible in many contexts. For instance, in the opinion dynamics modeling, it

is not realistic to assume that all interactions happen at the same time: agents are embedded in a physical continuous time, and interactions can be imagined to take place at random, for instance, in a pairwise fashion.

One of the most famous random consensus model is the gossip model. Fix a real number $q \in (0, 1)$ and a symmetric graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. At every time instant t, an edge $(u, v) \in \mathcal{E}$ is activated with uniform probability $|\mathcal{E}|^{-1}$, and nodes u and v exchange their states and produce a new state according to the equations

$$x_u(t + 1) = (1 - q)x_u(t) + qx_v(t)$$
$$x_v(t + 1) = qx_u(t) + (1 - q)x_v(t)$$

The states of the other units remain unchanged.

Will this dynamics lead to a consensus? If the same edge is activated at every time instant, clearly consensus will not be achieved. However, it can be shown that, with probability one, consensus will be reached (Boyd et al. 2006).

Consensus Dynamics with Stubborn Agents

In this entry, we investigate consensus dynamics models where some of the agents do not modify their own state (stubborn agents). These systems are of interest in socioeconomic models (Acemoglu et al. 2013).

Consider a symmetric connected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. We assume a splitting $\mathcal{V} = \mathcal{S} \cup \mathcal{R}$ with the understanding that agents in S are *stubborn* agents not changing their state, while those in $\mathcal{R}$ are *regular* agents whose state modifies in time according to a SRW consensus dynamics, namely,

$$x_u(t + 1) = \frac{1}{d_u} \sum_{v \in \mathcal{V}} (A_{\mathcal{G}})_{uv} x_v(t), \quad \forall u \in \mathcal{R}$$

By assembling the state of the regular and of the stubborn agents in vectors denoted, respectively, as $x^{\mathcal{R}}(t)$ and $x^{\mathcal{S}}(t)$, dynamics can be recast in matrix form as

$$\begin{aligned} x^{\mathcal{R}}(t + 1) &= Q^{11}x^{\mathcal{R}}(t) + Q^{12}x^{\mathcal{S}}(t) \\ x^{\mathcal{S}}(t + 1) &= x^{\mathcal{S}}(t) \end{aligned} \quad (5)$$

It can be proven that Q^{11} is asymptotically stable $((Q^{11})^t \to 0)$. Henceforth, $x^{\mathcal{R}}(t) \to x^{\mathcal{R}}(\infty)$ for $t \to +\infty$ with the limit opinions satisfying the relation

$$x^{\mathcal{R}}(\infty) = Q^{11}x^{\mathcal{R}}(\infty) + Q^{12}x^{\mathcal{S}}(0) \quad (6)$$

If we define $\Xi := (I - Q^{11})^{-1}Q^{12}$, we can write $x^{\mathcal{R}}(\infty) = \Xi x^{\mathcal{S}}(0)$. It is easy to see that Ξ has nonnegative elements and that $\sum_s \Xi_{us} = 1$ for all $u \in \mathcal{R}$: asymptotic opinions of regular agents are thus convex combinations of the opinions of stubborn agents. If all stubborn agents are in the same state x, then, consensus is reached by all agents in the point x. However, typically, consensus is not reached in such a system: we will discuss an example below.

There is a useful alternative interpretation of the asymptotic opinions. Interpreting the graph $\mathcal{G}$ as an electrical circuit where edges are unit resistors, relation (6) can be seen as a Laplace-type equation on the graph $\mathcal{G}$ with boundary conditions given by assigning the voltage $x^{\mathcal{S}}(0)$ to the stubborn agents. In this way, $x^{\mathcal{R}}(\infty)$ can be interpreted as the vector of voltages of the regular agents when stubborn agents have fixed voltage $x^{\mathcal{S}}(0)$. Thanks to the electrical analogy, we can compute the asymptotic opinion of the agents by computing the voltages in the various nodes in the graph. We propose a concrete application in the following example.

Example 5 (Stubborn agents in a line graph) Consider the line graph $L_N = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{1, 2, \ldots, N\}$ and where $\mathcal{E} = \{(u, u + 1), (u + 1, u) \mid u = 1, \ldots, N - 1\}$. Assume that $\mathcal{S} = \{1, N\}$ and $\mathcal{R} = \mathcal{V} \setminus \mathcal{S}$. Consider the graph as an electrical circuit. Replacing the line with a single edge connecting 1 and N having resistance $N - 1$ and applying Ohm's law, we obtain that the current flowing from 1 to N is equal to $\Phi = (N - 1)^{-1}[x_N^{\mathcal{S}}(0) - x_1^{\mathcal{S}}(0)]$. If we now fix an arbitrary node $v \in \mathcal{V}$ and applying again the same arguments in the part of graph from 1 to v, we obtain that the voltage at v, $x_v^{\mathcal{R}}(\infty)$ satisfies the relation $x_v^{\mathcal{R}}(\infty) - x_1^{\mathcal{S}}(0) = \Phi(v - 1)$. We thus obtain

$$x_v^{\mathcal{R}}(\infty) = x_1^{\mathcal{S}}(0) + \frac{v-1}{N-1}[x_N^{\mathcal{S}}(0) - x_1^{\mathcal{S}}(0)].$$

In Acemoglu et al. (2013), further examples are discussed showing how, because of the topology of the graph, different asymptotic configurations may show up. While in graphs presenting bottlenecks polarization phenomena can be recorded, in graphs where the convergence rate is low, there will be a typical asymptotic opinion shared by most of the regular agents.

Control and Optimization of Batch Processes

Dominique Bonvin
Laboratoire d'Automatique, École Polytechnique Fédérale de Lausanne (EPFL), 1015 Lausanne, Switzerland

Abstract

A batch process is characterized by the repetition of time-varying operations of finite duration. Due to the repetition, there are two independent "time" variables, namely, the run time during a batch and the batch counter. Accordingly, the control and optimization objectives can be defined for a given batch or over several batches. This entry describes the various control and optimization strategies available for the operation of batch processes. These include conventional feedback control, predictive control, iterative learning control, and run-to-run control on the one hand and model-based repeated optimization and model-free self-optimizing schemes on the other.

Keywords

Batch control; Batch process optimization; Dynamic optimization; Iterative learning control; Run-to-run control; Run-to-run optimization

Introduction

Batch processing is widely used in the manufacturing of goods and commodity products, in particular in the chemical, pharmaceutical, and food industries. These industries account for several billion US dollars in annual sales. Batch operation differs significantly from continuous operation. While in continuous operation the process is maintained at an economically desirable operating point, the process evolves continuously from an initial to a final time in batch processing. In the chemical industry, for example, since the design of a continuous plant requires substantial engineering effort, continuous operation is rarely

Implementation aspect	Control objectives	
	Run-time references $y_{ref}(t)$ or $y_{ref}[0,t_f]$	Run-end references z_{ref}
Online (within-run)	① Feedback control $u_k(t) \rightarrow y_k(t) \rightarrow y_k[0,t_f]$ ⬆ FBC	② Predictive control $\dot{u}_k(t) \rightarrow z_{pred,k}(t)$ ⬆ MPC
Iterative (run-to-run)	③ Iterative learning control $u_k[0,t_f] \rightarrow y_k[0,t_f]$ ⬆ ILC with run delay	④ Run-to-run control $\mathcal{U}(\pi_k) = u_k[0,t_f] \rightarrow z_k$ ⬆ R2R with run delay

Control and Optimization of Batch Processes, Fig. 1
Control strategies for batch processes. The strategies are classified according to the control objectives (horizontal division) and the implementation aspect (vertical division). Each objective can be met either online or iteratively over several batches depending on the type of measurements available. u_k represents the input vector for the kth batch, $u_k[0,t_f]$ the corresponding input trajectories, $y_k(t)$ the run-time outputs measured online, and z_k the run-end outputs available at the final time. FBC stands for "feedback control," MPC for "model predictive control," ILC for "iterative learning control," and R2R for "run-to-run control"

used for low-volume production. Discontinuous operations can be of the batch or semi-batch type. In batch operations, the products to be processed are loaded in a vessel and processed without material addition or removal. This operation permits more flexibility than continuous operation by allowing adjustment of the operating conditions and the final time. Additional flexibility is available in semi-batch operations, where products are continuously added by adjusting the feed rate profile. We use the term batch process to include semi-batch processes.

Batch processes dealing with reaction and separation operations include reaction, distillation, absorption, extraction, adsorption, chromatography, crystallization, drying, filtration, and centrifugation. The operation of batch processes involves recipes developed in the laboratory. A sequence of operations is performed in a prespecified order in specialized process equipment, yielding a fixed amount of product. The sequence of tasks to be carried out on each piece of equipment, such as heating, cooling, reaction, distillation, crystallization, and drying, is predefined. The desired production volume is then achieved by

repeating the processing steps on a predetermined schedule.

The main characteristics of batch process operations include the absence of steady state, the presence of constraints, and the repetitive nature. These characteristics bring both challenges and opportunities to the operation of batch processes (Bonvin 1998). The challenges are related to the fact that the available models are often poor and incomplete, especially since they need to represent a wider range of operating conditions than in the case of continuous processes. Furthermore, although product quality must be controlled, this variable is usually not available online but only at run end. On the other hand, opportunities stem from the fact that industrial chemical processes are often slow, which facilitates larger sampling periods and extensive online computations. In addition, the repetitive nature of batch processes opens the way to run-to-run process improvement (Bonvin et al. 2006). More information on batch processes and their operation can be found in Seborg et al. (2004) and Nagy and Braatz (2003). Next, we will successively address the control and the optimization of batch processes.

Control of Batch Processes

Control of batch processes differs from control of continuous processes in two main ways. First, since batch processes have no steady-state operating point, at least some of the set points are time-varying profiles. Second, batch processes are repeated over time and are characterized by two independent variables, the run time t and the run counter k. The independent variable k provides additional degrees of freedom for meeting the control objectives when these objectives do not necessarily have to be completed in a single batch but can be distributed over several successive batches. This situation brings into focus the concept of run-end outputs, which need to be controlled but are only available at the completion of the batch. The most common run-end output is product quality. Consequently, the control of batch processes encompasses four different strategies (Fig. 1):

1. *Online control of run-time outputs.* This control approach is similar to that used in continuous processing. However, although some controlled variables, such as temperature in isothermal operation, remain constant, the key process characteristics, such as process gain and time constants, can vary considerably because operation occurs along state trajectories rather than at a steady-state operating point. Hence, adaptation in run time t is needed to handle the expected variations. Feedback control is implemented using PID techniques or more sophisticated alternatives (Seborg et al. 2004).

2. *Online control of run-end outputs.* In this case it is necessary to predict the run-end outputs z based on measurements of the run-time outputs y. Model predictive control (MPC) is well suited to this task (Nagy and Braatz 2003). However, the process models available for prediction are often simplified and thus of limited accuracy.

3. *Iterative control of run-time outputs.* The manipulated variable profiles can be generated using iterative learning control (ILC), which exploits information from previous runs

(Moore 1993). This strategy exhibits the limitations of open-loop control with respect to the current run, in particular the fact that there is no feedback correction for run-time disturbances. Nevertheless, this scheme is useful for generating a time-varying feedforward input term.

4. *Iterative control of run-end outputs.* In this case the input profiles are parameterized as $u_k[0, t_f] = \mathcal{U}(\pi_k)$ using the input parameters π_k. The batch process is thus seen as a static map between the input parameters π_k and the run-end outputs z_k (Francois et al. 2005).

It is also possible to combine online and run-to-run control for both y and z. However, in such a combined scheme, care must be taken so that the online and run-to-run corrective actions do not oppose each other. Stability during run time and convergence in run index must be guaranteed (Srinivasan and Bonvin 2007a).

Optimization of Batch Processes

The process variables undergo significant changes during batch operation. Hence, the major objective in batch operations is not to keep the system at optimal constant set points but rather to determine input profiles that optimize an objective function expressing the system performance.

Problem Formulation

A typical optimization problem in the context of batch processes is

$$\min_{u_k[0,t_f]} J_k = \phi\big(x_k(t_f)\big)$$
$$+ \int_0^{t_f} L\big(x_k(t), u_k(t), t\big)\, dt \quad (1)$$

subject to

$$\dot{x}_k(t) = F\big(x_k(t), u_k(t)\big), \quad x_k(0) = x_{k,0} \quad (2)$$
$$S\big(x_k(t), u_k(t)\big) \le 0, \quad T\big(x_k(t_f)\big) \le 0, \quad (3)$$

where x represents the state vector, J the scalar cost to be minimized, S the run-time constraints, T the run-end constraints, and t_f the final time.

In constrained optimal control problems, the solution often lies on the boundary of the feasible region. Batch processes involve run-time constraints on inputs and states as well as run-end constraints.

Optimization Strategies

As can be seen from the cost objective (1), optimization requires information about the complete run and thus cannot be implemented in real time using only online measurements. Some information regarding the future of the run is needed in the form of either a process model capable of prediction or measurements from previous runs. Accordingly, measurement-based optimization methods can be classified depending on whether or not a process model is used explicitly for implementation, as illustrated in Fig. 2 and discussed next:

1. *Online explicit optimization.* This approach is similar to model predictive control (Nagy and Braatz 2003). Optimization uses a process model explicitly and is repeated whenever a new set of measurements becomes available. This scheme involves two steps, namely,

updating the initial conditions for the subsequent optimization (and optionally the parameters of the process model) and numerical optimization based on the updated process model (Abel et al. 2000). Since both steps are repeated as measurements become available, the procedure is also referred to as repeated online optimization. The weakness of this method is its reliance on the model; if the model is not updated, its accuracy plays a crucial role. However, when the model is updated, there is a conflict between parameter identification and optimization since parameter identification requires persistency of excitation, that is, the inputs must be sufficiently varied to uncover the unknown parameters, a condition that is usually not satisfied when near-optimal inputs are applied. Note that, instead of computing the input $u_k^*[t, t_f]$, it is also possible to use a receding horizon and compute only $u_k^*[t, t + T]$, with T the control horizon (Abel et al. 2000).

2. *Online implicit optimization.* In this scenario, measurements are used to update the inputs directly, that is, without the intermediary of a process model. Two classes of techniques can be identified. In the first class, an update law that approximates the optimal solution

Implementation aspect	Use of process model	
	Explicit optimization (with process model)	Implicit optimization (without process model)
Online (within-run)	① *Repeated online optimization* $y_k[0,t] \xrightarrow{\text{EST}} \hat{x}_k(t) \xrightarrow{\text{OPT}} u_k^*[t,t_f]$ ⇡ repeat online	② *Online input update using measurements* $y_k(t) \xrightarrow{\text{Approx. of opt. solution}} u_k^*(t)$ $y_k[0,t] \xrightarrow{\text{NCO prediction}} NCO \longrightarrow u_k^*(t)$
Iterative (run-to-run)	③ *Repeated run-to-run optimization* $y_k[0,t_f] \xrightarrow{\text{IDENT}} \hat{\theta}_k \xrightarrow{\text{OPT}} u_{k+1}^*[0,t_f]$ ⇡ repeat with run delay	④ *Run-to-run input update using measurements* $y_k[0,t_f] \xrightarrow{\text{NCO evaluation}} NCO \longrightarrow u_{k+1}^*[0,t_f]$ ⇡ repeat with run delay

Control and Optimization of Batch Processes, Fig. 2 Optimization strategies for batch processes. The strategies are classified according to whether or not a process model is used for implementation (horizontal division). Furthermore, each class can be implemented either online

or iteratively over several runs (vertical division). EST stands for "estimation," IDENT for "identification," OPT for "optimization," and NCO for "necessary conditions of optimality"

is sought. For example, a neural network is trained with data corresponding to optimal behavior for various uncertainty realizations and used to update the inputs (Rahman and Palanki 1996). The second class of techniques relies on transforming the optimization problem into a control problem that enforces the necessary conditions of optimality (NCO) (Srinivasan and Bonvin 2007b). The NCO involve constraints that need to be made active and sensitivities that need to be pushed to zero. Since some of these NCO are evaluated at run time and others at run end, the control problem involves both run-time and run-end outputs. The main issue is the measurement or estimation of the controlled variables, that is, the constraints and sensitivities that constitute the NCO.

3. *Iterative explicit optimization.* The steps followed in run-to-run explicit optimization are the same as in online explicit optimization. However, there is substantially more data available at the end of the run as well as sufficient computational time to refine the model by updating its parameters and, if needed, its structure. Furthermore, data from previous runs can be collected for model update (Rastogi et al. 1992). As with online explicit optimization, this approach suffers from the conflict between estimation and optimization.

4. *Iterative implicit optimization.* In this scenario, the optimization problem is transformed into a control problem, for which the control approaches in the second row of Fig. 1 are used to meet the run-time and run-end objectives (Francois et al. 2005). The approach, which is conceptually simple, might be experimentally expensive since it relies more on data.

These complementary measurement-based optimization strategies can be combined by implementing some aspects of the optimization online and others on a run-to-run basis. For instance, in explicit schemes, the states can be estimated online, while the model parameters can be estimated on a run-to-run basis. Similarly, in implicit optimization, approximate update

laws can be implemented online, leaving the responsibility for satisfying terminal constraints and sensitivities to run-to-run controllers.

Summary and Future Directions

Batch processing presents several challenges. Since there is little time for developing appropriate dynamic models, there is a need for improved data-driven control and optimization approaches. These approaches require the availability of online concentration-specific measurements such as chromatographic and spectroscopic sensors, which are not yet readily available in production.

Technically, the main operational difficulty in batch process improvement lies in the presence of run-end outputs such as final quality, which cannot be measured during the run. Although model-based solutions are available, process models in the batch area tend to be poor. On the other hand, measurement-based optimization for a given batch faces the challenge of having to know about the future to act during the batch. Consequently, the main research push is in the area of measurement-based optimization and the use of data from both the current and previous batches for control and optimization purposes.

Control Applications in Audio Reproduction

Yutaka Yamamoto
Department of Applied Analysis and Complex Dynamical Systems, Graduate School of Informatics, Kyoto University, Kyoto, Japan

Abstract

This entry gives a brief overview of the recent developments in audio sound reproduction via modern sampled-data control theory. We first review basics in the current sound processing technology and then proceed to the new idea derived from sampled-data control theory, which is different from the conventional Shannon paradigm based on the perfect band-limiting hypothesis. The hybrid nature of sampled-data systems provides an optimal platform for dealing with signal

processing where the ultimate objective is to reconstruct the original analog signal one started with. After discussing some fundamental problems in the Shannon paradigm, we give our basic problem formulation that can be solved using modern sampled-data control theory. Examples are given to illustrate the results.

Keywords

Introduction: Status Quo

Consider the problem of reproducing sounds from recorded media such as compact discs. The current CD format is recorded at the sampling frequency 44.1 kHz. It is commonly claimed that the highest frequency for human audibility is 20 kHz, whereas the upper bound of reproduction in this format is believed to be the half of 44.1 kHz, i.e., 22.1 kHz, and hence, this format should have about 10 % margin against the alleged audible limit of 20 kHz.

CD players of early days used to process such digital signals with the simple zero-order hold at this frequency, followed by an analog low-pass filter. This process requires a sharp low-pass characteristic to cut out unnecessary high frequency beyond 20 kHz. However, a sharp cutoff low-pass characteristic inevitably requires a high-order filter which in turn introduces a large amount of phase shift distortion around the cutoff frequency.

To circumvent this defect, there was introduced the idea of oversampling DA converter that is realized by the combination of a digital filter and a low-order analog filter (Zelniker and Taylor 1994). This is based on the following principle:

Let $\{f(nh)\}_{n=-\infty}^{\infty}$ be a discrete-time signal obtained from a continuous-time signal $f(\cdot)$ by sampling it with sampling period h. The *upsampler* appends the value 0, $M - 1$ times, between two adjacent sampling points:

**Control Applications in
Audio Reproduction,
Fig. 1** Upsampler for
$M = 2$
$$(\uparrow Mw)[k] := \begin{cases} w(\ell), & k = M\ell \\ 0, & \text{elsewhere.} \end{cases} \quad (1)$$

See Fig. 1 for the case $M = 2$. This has the effect of making the unit operational time M times faster.

The bandwidth will also be expanded by M times and the *Nyquist frequency* (i.e., half the sampling frequency) becomes $M\pi/h$ [rad/sec]. As we see in the next section, the Nyquist frequency is often regarded as the true bandwidth of the discrete-time signal $\{f(nh)\}_{n=-\infty}^{\infty}$. But this upsampling process just insert zeros between sampling points, and the real information contents (the true bandwidth) is not really expanded. As a result, the copy of the frequency content for $[0, \pi/h)$ appears as a mirror image repeatedly over the frequency range above π/h. This distortion is called *imaging*. In order to avoid the effect of such mirrored frequency components, one often truncates the frequency components beyond the (original) Nyquist frequency via a digital low-pass filter that has a sharp roll-off characteristic. One can then complete the digital to analog (DA) conversion process by postposing a slowly decaying analog filter. This is the idea of an *oversampling DA converter* (Zelniker and Taylor 1994). The advantage here is that by allowing a much wider frequency range, the final analog filter can be a low-order filter and hence yields a relatively small amount of phase distortion supported in part by the linear-phase characteristic endowed on the digital filter preceding it.

Signal Reconstruction Problem

As before, consider the sampled discrete-time signal $\{f(nh)\}_{n=-\infty}^{\infty}$ obtained from a continuous-time signal f. The main question is how we can recover the original continuous-time signal $f(\cdot)$ from sampled data. This is clearly an ill-posed problem without any assumption on f because there are infinitely many functions that can match the sampled data $\{f(nh)\}_{n=-\infty}^{\infty}$. Hence, one has to impose a reasonable a priori assumption on f to sensibly discuss this problem.

The following sampling theorem gives one answer to this question:

Theorem 1 *Suppose that the signal $f \in L^2$ is perfectly band-limited, in the sense that there exists $\omega_0 \leq \pi/h$ such that the Fourier transform $\hat{f}$ of f satisfies*

$$\hat{f}(\omega) = 0, \quad |\omega| \geq \omega_0,. \quad (2)$$

Then

$$f(t) = \sum_{n=-\infty}^{\infty} f(nh)\frac{\sin \pi(t/h - n)}{\pi(t/h - n)}. \quad (3)$$

This theorem states that if the signal f does not contain any high-frequency components beyond the *Nyquist frequency* π/h, then the original signal f can be uniquely reconstructed from its sampled-data $\{f(nh)\}_{n=-\infty}^{\infty}$. On the other hand, if this assumption does not hold, then the result does not necessarily hold. This is easy to see via a schematic representation in Fig. 2.

If we sample the sinusoid in the upper figure in Fig. 2, these sampled values would turn out to be compatible with another sinusoid with much lower frequency as the lower figure shows. In other words, this sampling period does not have enough resolution to distinguish these two sinusoids. The maximum frequency below where there does not occur such a phenomenon is the Nyquist frequency. The sampling theorem above asserts that it is half of the sampling frequency $2\pi/h$, that is, π/h [rad/sec]. In other words, if
Control Applications in Audio Reproduction, Fig. 2
Aliasing

we can assume that the original signal contains no frequency components beyond the Nyquist frequency, then one can uniquely reconstruct the original analog signal f from its sampled-data $\{f(nh)\}_{n=-\infty}^{\infty}$. On the other hand, if this assumption does not hold, the distortion depicted in Fig. 2 occurs; this is called *aliasing*.

This is the content of the sampling theorem. It has been widely accepted as the basis for digital signal processing that bridges analog to digital. Concrete applications such as CD, MP3, or images are based on this principle in one way or another.

Difficulties

However, this paradigm (hereafter the *Shannon paradigm*) of the perfect band-limiting hypothesis and the resulting sampling theorem renders several difficulties as follows:

- The reconstruction formula (3) is not causal, i.e., one needs future sampled values to reconstruct the present value $f(t)$. One can remedy this defect by allowing a certain amount of delay in reconstruction, but this delay can depend on how fast the formula converges.
- This formula is known to decay slowly; that is, we need many terms to approximate if we use this formula as it is.
- The perfect band-limiting hypothesis is hardly satisfied in reality. For example, for CDs, the

Nyquist frequency is 22.05 kHz, and the energy distribution of real sounds often extends way over 20 kHz.
- To remedy this, one often introduces a band-limiting low-pass filter, but it can introduce distortions due to the Gibbs phenomenon, due to a required sharp decay in the frequency domain. See Fig. 3.

This is the Gibbs phenomenon well known in Fourier analysis. A sharp truncation in the frequency domain yields such a ringing effect.

In view of such drawbacks, there has been revived interest in the extension of the sampling theorem in various forms since the 1990s. There is by now a stream of papers that aim at studying signal reconstruction under the assumption of nonideal signal acquisition devices; an excellent survey is given in Unser (2000). In this research framework, the incoming signal is supposed to be acquired through a nonideal analog filter (acquisition device) and sampled, and then the reconstruction process attempts to recover the original signal. The idea is to place the problem into the framework of the (orthogonal or oblique) projection theorem in a Hilbert space (usually L^2) and then project the signal space to the subspace generated by the shifted reconstruction functions. It is often required that the process give a *consistent* result, i.e., if we subject the reconstructed signal to the whole process again, it should yield the same sampled values from which it was reconstructed (Unser and Aldroubi 1994).

In what follows, we take a similar viewpoint, that is, the incoming signals are acquired through a nonideal filter, but develop a methodology different from the projection method, relying on sampled-data control theory.
The Signal Class

We have seen that the perfect band-limiting hypothesis is restrictive. Even if we adopt it, it is a fairly crude model for analog signals to allow for a more elaborate study.

Let us now pose the question: *What class of functions should we process in such systems?*

Control Applications in Audio Reproduction, Fig. 3 Ringing due to the Gibbs phenomenon
Control Applications in Audio Reproduction, Fig. 4 Error system for sampled-data design

Consider the situation where one plays a musical instrument, say, a guitar. A guitar naturally has a frequency characteristic. When one picks a string, it produces a certain tone along with its harmonics, as well as a characteristic transient response. All these are governed by a certain frequency decay curve, demanded by the physical characteristics of the guitar. Let us suppose that such a frequency decay is governed by a rational transfer function $F(s)$, and it is driven by varied exogenous inputs.

Consider Fig. 4. The exogenous analog signal $w_c \in L^2$ is applied to the analog filter $F(s)$. This $F(s)$ is not an ideal filter and hence its bandwidth is not limited below the Nyquist frequency. The signal w_c drives $F(s)$ to produce the target analog signal y_c, which should be the signal to be reconstructed. It is then sampled by sampler $\mathcal{S}_h$ and becomes the recorded or transmitted digital signal y_d. The objective here is to reconstruct the target analog signal y_c out of this sampled signal y_d. In order to recover

the frequency components beyond the Nyquist frequency, one needs a faster sampling period, so we insert the upsampler $\uparrow L$ to make the sampling period h/L. This upsampled signal is processed by digital filter $K(z)$ and then becomes a continuous-time signal again by going through the hold device $\mathcal{H}_{h/L}$. It will then be processed by analog filter $P(s)$ to be smoothed out. The obtained signal is then compared with delayed analog signal $y_c(t - mh)$ to form the delayed error signal e_c. The objective is then to make this error e_c as small as possible. The reason for allowing delay e^{-mhs} is to accommodate certain processing delays. This is the idea of the block diagram Fig. 4.

The performance index we minimize is the induced norm of the transfer operator T_{ew} from w_c to e_c:

$$\|T_{ew}\|_\infty := \sup_{w_c \neq 0} \frac{\|e_c\|_2}{\|w_c\|_2}. \qquad (4)$$

In other words, the H^∞-norm of the sampled-data control system Fig. 4. Our objective is then to solve the following problem:

Filter Design Problem

Given the system specified by Fig. 4. For a given performance level $\gamma > 0$, find a filter $K(z)$ such that

$$\|T_{ew}\|_\infty < \gamma.$$

This is a sampled-data H^∞ (sub-)optimal control problem. This can be solved by using the standard solution method for sampled-data control systems (Chen and Francis 1995a; Yamamoto 1999; Yamamoto et al. 2012). The only anomaly here is that the system in Fig. 4 contains a delay element e^{-mhs} which is infinite dimensional. However, by suitably approximating this delay by successive series of shift registers, one can convert the problem to an appropriate finite-dimensional discrete-time problem (Yamamoto et al. 1999, 2002, 2012).

This problem setting has the following features:

1. One can optimize the continuous-time performance under the constraint of discrete-time filters.
2. By setting the class of input functions as L^2 functions band-limited by $F(s)$, one can capture the continuous-time error signal e_c and its worst-case norm in the sense of (4).

The first feature is due to the advantage of sampled-data control theory. It is a great advantage of sampled-data control theory that allows the mixture of continuous- and discrete-time components. This is in marked contrast to the Shannon paradigm where continuous-time performance is really demanded by the artificial perfect band-limiting hypothesis.

The second feature is an advantage due to H^∞ control theory. Naturally, we cannot have an access to each *individual* error signal e_c, but we can still control the *overall performance* from w_c to e_c in terms of the H^∞ norm that guarantees the worst-case performance. This is in clear contrast with the classical case where only a representative response, e.g., impulse response

in the case of H^2, is targeted. Furthermore, since we can control the continuous-time performance of the worst-case error signal, the present method can indeed minimize (continuous-time) phase errors. This is an advantage usually not possible with conventional methods since they mainly discuss the gain characteristics of the designed filters only. By the very property of minimizing the H^∞ norm of the *continuous-time error signal e_c*, the present method can even control the phase errors and yield much less phase distortion even around the cutoff frequency.

Figure 5 shows the response of the proposed sampled-data filter against a rectangular wave, with a suitable first- or second-order analog filter $F(s)$; see Yamamoto et al. (2012) for more details. Unlike Fig. 3, the overshoot is controlled to be minimum.

The present method has been patented (Fujiyama et al. 2008; Yamamoto 2006; Yamamoto and Nagahara 2006) and implemented into sound processing LSI chips as a core technology by Sanyo Semiconductors and successfully used in mobile phones, digital voice recorders, and MP3 players; their cumulative production has exceeded 40 million units as of the end of 2012.

Summary and Future Directions

We have presented basic ideas of new signal processing theory derived from sampled-data control theory. The theory has the advantage that is not possible with the conventional projection methods, whether based on the perfect band-limiting hypothesis or not.

The application of sampled-data control theory to digital signal processing was first made by Chen and Francis (1995b) with performance measure in the discrete-time domain; see also Hassibi et al. (2006). The present author and his group have pursued the idea presented in this entry since 1996 (Khargonekar and Yamamoto 1996). See Yamamoto et al. (2012) and references therein. For the background of sampled-data

Control Applications in Audio Reproduction, Fig. 5 Response of the proposed sampled-data filter against a rectangular wave
control theory, consult, e.g., Chen and Francis (1995a) and Yamamoto (1999).

The same philosophy of emphasizing the importance of analog performance was proposed and pursued recently by Unser and co-workers (1994), Unser (2005), and Eldar and Dvorkind (2006). The crucial difference is that they rely on L^2/H^2 type optimization and orthogonal or oblique projections, which are very different from our method here. In particular, such projection methods can behave poorly for signals outside the projected space. The response shown in Fig. 3 is a typical such example.

Applications to image processing is discussed in Yamamoto et al. (2012). An application to Delta-Sigma DA converters is studied in Nagahara and Yamamoto (2012). Again, the crux of the idea is to assume a signal generator model and then design an optimal filter in the sense of Fig. 4 or a similar diagram with the same idea. This idea should be applicable to a much wider class of problems in signal processing and should prove to have more impact.

Some processed examples of still and moving images are downloadable from the site: http://www-ics.acs.i.kyoto-u.ac.jp/~yy/

For sampling theorem, see Shannon (1949), Unser (2000), and Zayed (1996), for example. Note, however, that Shannon himself (1949) did not claim originality on this theorem; hence, it is misleading to attribute this theorem solely to Shannon. See Unser (2000) and Zayed (1996) for some historical accounts. For a general background in signal processing, Vetterli et al. (2013) is useful.

Control for High-Speed Nanopositioning

S.O. Reza Moheimani
School of Electrical Engineering & Computer Science, The University of Newcastle, Callaghan, NSW, Australia

Abstract

Over the last two and a half decades we have observed astonishing progress in the field of nanotechnology. This progress is largely due to the invention of Scanning Tunneling Microscope (STM) and Atomic Force Microscope (AFM) in the 1980s. Central to the operation of AFM and STM is a nanopositioning system that moves a sample or a probe, with extremely high precision, up to a fraction of an Angstrom, in certain applications. This note concentrates on the fundamental role of feedback, and the need for model-based control design methods in improving accuracy and speed of operation of nanopositioning systems.

Keywords

Atomic force microscopy; High-precision mechatronic systems; Nanopositioining; Scanning probe microscopy

Introduction

Controlling motion of an actuator to within a single atom, known as nanopositioning, may seem as an impossible task. Yet, it has become a key requirement in many systems to emerge in recent years. In scanning probe microscopy nanopositioning is needed to scan a probe over a sample surface for imaging and to control the interaction between the probe and the surface during interrogation and manipulation (Meyer et al. 2004). Nanopositioning is the enabling technology for mask-less lithography tools under development to replace optical lithography systems (Vettiger et al. 2002). Novel nanopositioning

tools are required for positioning of wafers and for mask alignment in the semiconductor industry (Verma et al. 2005). Nanopositioning systems are vital in molecular biology for imaging, alignment, and nanomanipulation in applications such as DNA analysis (Meldrum et al. 2001) and nanoassembly (Whitesides and Christopher Love 2001). Nanopositioning is an important technology in optical alignment systems (Krogmann 1999). In data storage systems, nanometer-scale precision is needed for emerging probe-storage devices, for dual-stage hard-disk drives, and for next generation tape drives (Cherubini et al. 2012).

The Need for High-Speed Nanopositioning

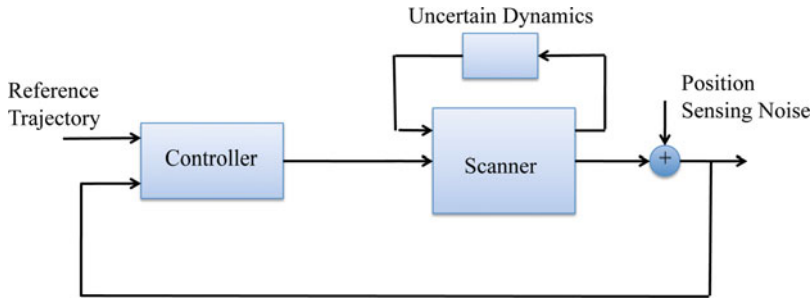
In all applications of nanopositioning, there is a significant and growing demand for high speeds. The ability to operate a nanopositioner at a bandwidth of tens of kHz, as opposed to today's hundreds of Hz, is the key to unlocking countless technological possibilities in the future (Gao et al. 2000; Pantazi et al. 2008; Salapaka 2003; Sebastian et al. 2008b; Yong et al. 2012). The atomic force microscope (AFM) is an example of such technologies. A typical commercial atomic force microscope is a slow device, taking up to a minute or longer to generate an image. Such imaging speeds are too slow to investigate phenomena with fast dynamics. For example, rapid biological processes that occur in seconds, such as rapid movement of cells or fast dehydration and denaturation of collagen, are too fast to be observed by a typical commercial AFM (Zou et al. 2004). A key obstacle in realizing high-speed and video-rate atomic force microscopy is the limited speed of nanopositioners.

The Vital Role of Feedback Control in High-Speed Nanopositioning

The systems described above depend on a precision mechatronic device, known as a *nanopositioner*, or a *scanner* for their operation.
Control for High-Speed Nanopositioning, Fig. 1 A 3DoF flexure-guided high-speed nanopositioner (Yong et al. 2013). The three axes are actuated independently using piezoelectric stack actuators. Movement of lateral axes is measured using capacitive sensors

A high-speed scanner is shown in Fig. 1. In all applications where nanopositioning is a necessity, the key objective is to make the scanner follow, or track, a given reference trajectory (Devasia et al. 2007). A large number of control design methods have been proposed for this purpose, including feedforward control (Clayton et al. 2009), feedback control (Salapaka 2003), and combinations of those (Yong et al. 2009). These control techniques are required in order to compensate for the mechanical resonances of the scanner as well as for various nonlinearities and uncertainties in the dynamics of the nanopositioner. At low speeds, feedforward techniques are usually sufficient to address many of the arising challenges. However, over a wide bandwidth, model uncertainties, sensor noise, and mechanical cross-couplings become significant, and hence feedback control becomes essential to achieve the requisite nanoscale accuracy and precision at high speeds (Devasia et al. 2007; Salapaka 2003).

Control Design Challenges

A feedback loop typically encountered in nanopositioning is illustrated in Fig. 2. The purpose of the feedback controller is to control


Control for High-Speed Nanopositioning, Fig. 2 A feedback loop typically encountered in nanopositioning. Purpose of the controller is to control the position of the scanner such that it follows the intended reference trajectory based on the position measurement obtained from a position sensor

the position of the scanner such that it follows a given reference trajectory based on the measurement provided by a displacement sensor. The resulting tracking error contains both deterministic and stochastic components. Deterministic errors are typically due to insufficient closed-loop bandwidth. They may also arise from excitation of mechanical resonant modes of the scanner or actuator nonlinearities such as piezoelectric hysteresis and creep (Croft et al. 2001). The factors that limit the achievable closed-loop bandwidth include phase delays and non-minimum phase zeros associated with the actuator and scanner dynamics (Devasia et al. 2007). The dynamics of the nanopositioner, the controller, and the reference trajectory selected for scanning play a key role in minimizing the deterministic component of the tracking error.

Tracking errors of a stochastic nature mostly arise from external noise and vibrations and from position measurement noise. External noise and vibrations can be significantly reduced by operating the nanopositioner in a controlled environment. However, dealing with the measurement noise is a significant challenge (Sebastian et al. 2008a). The feedback loop allows the sensing noise to generate a random positioning error that deteriorates the positioning precision. Increasing the closed-loop bandwidth (to decrease the deterministic errors) tends to worsen this effect. Low sensitivity to measurement noise is, therefore, a key requirement in feedback control design for high-speed nanopositioning and a very hard problem to address.

Summary and Future Directions

While high-precision nanoscale positioning systems have been demonstrated at low speeds, despite an intensive international race spanning several years, the longstanding challenge remains to achieve high-speed motion and positioning with Ångstrom-level accuracy. Overcoming this barrier is believed to be the necessary catalyst for emergence of ground breaking innovations across a wide range of scientific and technological fields. Control is a critical technology to facilitate the emergence of such systems.

Control Hierarchy of Large Processing Plants: An Overview

Cesar de Prada
Departamento de Ingeniería de Sistemas y Automática, University of Valladolid, Valladolid, Spain

Abstract

This entry provides an overview of the so-called control pyramid, which organizes the different types of control tasks in a processing plant in a set of interconnected layers, from basic control and instrumentation to plant-wide economic optimization. These layers have different functions, all of them necessary for the optimal functioning of large processing plants.

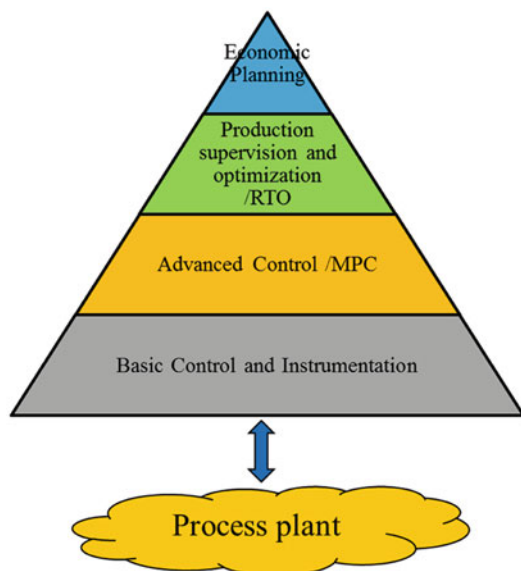
Keywords

Control hierarchy; Control pyramid; Model-predictive control; Optimization; Plant-wide control; Real-time optimization

Introduction

Operating a process plant is a complex task involving many different aspects ranging from the control of individual pieces of equipment and of process units to the management of the plant or factory as a whole, including relations with other plants or suppliers.

From the control point of view, the corresponding tasks are traditionally organized in several layers, placing in the bottom the ones closer to the physical processes and in the top those closer to plant-wide management, forming the so-called control pyramid represented in Fig. 1.

The process industry currently faces many challenges, originated from factors such as increased competition among companies and better global market information, new environmental regulations and safety standards, improved quality, or energy efficiency requirements. Many years ago, the main tasks were associated to the


Control Hierarchy of Large Processing Plants: An Overview, Fig. 1 The control pyramid

correct and safe functioning of the individual process units and to the global management of the factory from the point of view of organization and economy. Therefore, only the lower and top layers of the control pyramid were realized by computer-based systems, whereas the intermediate tasks were largely performed by human operators and managers, but more and more the intermediate layers are gaining importance in order to face the abovementioned challenges.

Above the physical plant represented in Fig. 1, there is a layer related to instrumentation and basic control, devoted to obtaining direct process information and maintaining selected process variables close to their desired targets by means of local controllers. Motivated by the need for more efficient operation and better-quality assurance, an improvement of this basic control can be obtained using control structures such as cascades, feed forwards, ratios, and selectors. This is called advanced control in industry, but not in academia, where the word is reserved for more sophisticated controls.

A big step forward took place in the control field with the introduction of model-based predictive control (MBPC/MPC) in the late 1970s

and 1980s, (▶ Industrial MPC of Continuous Processes; Camacho and Bordóns (2004)). MPC aims at regulating a process unit as a whole considering all manipulated and controlled variables simultaneously. It handles all interactions, disturbances, and process constraints using a process model in order to compute the control actions that optimize a control performance index. MPC is built on top of the basic control loops and partly replaces the complex control structures of the advanced control layer adding new functionalities and better control performance. The improvements in control quality and the management of constraints and interactions of the model-predictive controllers open the door for the implementation of local economic optimization. Linked to the MPC controller and taking advantage of its model, an optimizer may look for the best operating point of the unit by computing the controller set points that optimize an economic cost function of the process unit considering the operational constraints of the unit. This task is usually formulated and solved as a linear programming (LP) problem, i.e., based on linear or linearized economic models and cost function (see Fig. 2).

A natural extension of these ideas was to consider the interrelations among the different parts of the processing plants and to look for the steady-state operating point that provides the best economic return and minimum energy expense or optimizes any other economic criterion while satisfying the global production aims and constraints. These optimization tasks are known as real-time optimization (RTO) (▶ Real-Time Optimization of Industrial Processes) and form another layer of the control pyramid.

Finally, when we consider the whole plant operation, obvious links between the RTO and the planning and economic management of the company appear. In particular, the organization and optimization of the flows of raw materials, purchases, etc., involved in the supply chains present important challenges that are placed in the top layer of Fig. 1.

This entry provides an overview of the different layers and associated tasks so that the
Control Hierarchy of Large Processing Plants: An Overview, Fig. 2 MPC implementation with a local optimizer

reader can place in context the different controllers and related functionalities and tools, as well as appreciate the trends in process control focusing the attention toward the higher levels of the hierarchy and the optimal operation of large-scale processes.

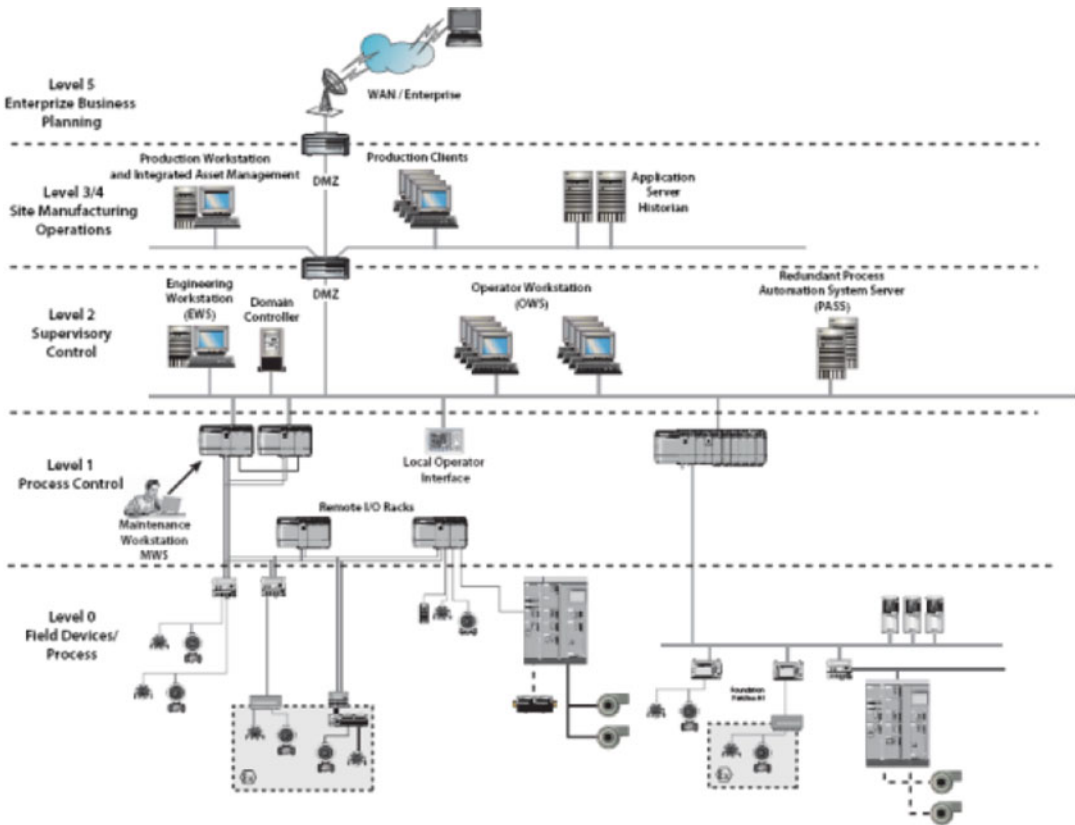
An Alternative View

The implementation in a process factory of the tasks and layers previously mentioned is possible nowadays due to important advances in many fields, such as modeling and identification, control and estimation, optimization methods, and, in particular, software tools, communications, and computing power. Today it is rather common to find in many process plants an information network that follows also a pyramidal structure represented in Fig. 3.

At the bottom, there is the instrumentation layer that includes, besides sensors and actuators connected by the classical analog 4–20 mA signals, possibly enhanced by the transmission of information to and from the sensors by the HART protocol, digital field buses and smart transmitters and actuators that incorporate improved information and intelligence. New functionalities, such as remote calibration, filtering, self-test, and disturbance compensation, provide more accurate measurements that contribute to improving the functioning of local controllers, in the same way as that of new methods and tools available nowadays for instrument monitoring and fault detection and diagnosis. The increased

installation of wireless transmitters and the advances in analytical instrumentation will lead, without doubt, to the development of a stronger information base to support better decisions and operations in the plants.

Information from transmitters is collected in the control rooms that are the core of the second layer. Many of them are equipped with distributed control systems (DCS) that implement monitoring and control tasks. Field signals are received in the control cabinets where a large number of microprocessors execute the data acquisition and regulatory control tasks, sending signals back to the field actuators. Internal buses connect the controllers with the computers that support the displays of the human-machine interface (HMI) for the plant operators of the control room. In the past, DCS were mostly in charge of the regulatory control tasks, including basic control, alarm management, and historians, while interlocking systems related to safety and sequences related to batch operations were implemented either in the DCS or in programmable logic controllers (PLCs): ▶ Programmable Logic Controllers. Today, the bounds are not so clear, due to the increase of the computing power of the PLCs and the added functionalities of the DCS. Safety instrumented systems (SIS) for the maintenance of plant safety are usually implemented in dedicated PLCs, if not hard-wired, but for the rest of the functions, a combination of PLC-like processors with I/O cards and SCADAs (Supervision, Control, And Data Acquisition Systems) is the prevailing architecture. SCADAs act as HMI and information systems collecting large amounts of data that can be used at other levels with different purposes.

Above the basic and advanced control layer, using the information stored in the SCADA as well as other sources, there is an increased number of applications covering diverse fields. Figure 3 depicts the perspective of the computing and information flow architecture and includes a level called supervisory control, placed in direct connection with the control room and the production tasks. It includes, for instance, MPC with local optimizers, statistical process control (SPC) for quality and production


**Control Hierarchy of Large Processing Plants: An Overview, Fig. 3** Information network in a modern process plant

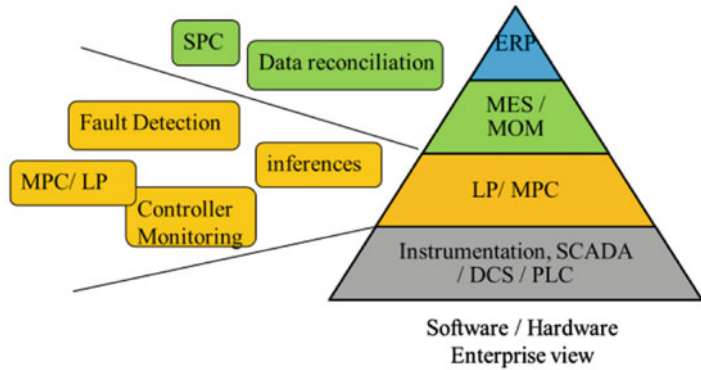
supervision (▶ Multiscale Multivariate Statistical Process Control), data reconciliation, inferences and estimation of unmeasured quantities, fault detection and diagnosis, or performance controller monitoring (▶ Controller Performance Monitoring) (CPM).

The information flow becomes more complex when we move up the basic control layer, looking more like a web than a pyramid when we enter the world of what can be called generally as asset (plant and equipment) management: a collection of different activities oriented to sustain performance and economic return, considering their entire cycle of life and, in particular, aspects such as maintenance, efficiency, or production organization. Above the supervisory layer, one can usually distinguish at least two levels denoted generically as manufacturing execution systems (MES) and enterprise resource planning (ERP) (Scholten 2009) as can be seen in Fig. 4.

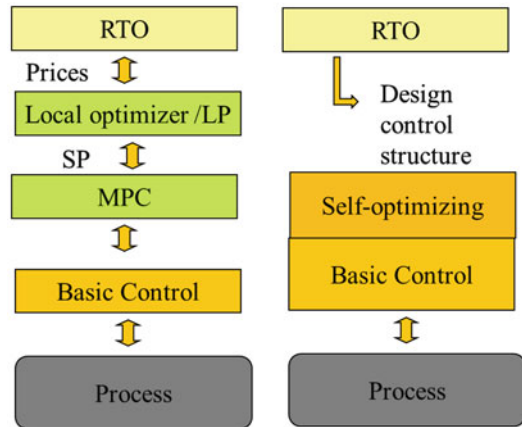
MES are information systems that support the functions that a production department must perform in order to prepare and to manage work instructions, schedule production activities, monitor the correct execution of the production process, gather and analyze information about the production process, and optimize procedures. Notice that regarding the control of process units, up to this level no fundamental differences appear between continuous and batch processes. But at the MES level, which corresponds to RTO of Fig. 1, many process units may be involved, and the tools and problems are different, the main task in batch production being the optimal scheduling of those process units (▶ Scheduling of Batch Plants; Mendez et al. 2006).

MES are part of a larger class of systems called manufacturing operation management (MOM) that cover not only the management of production operations but also other functions

Control Hierarchy of Large Processing Plants: An Overview, Fig. 4 Software/hardware view

Software / Hardware
Enterprise view


such as maintenance, quality, laboratory information systems, or warehouse management. One of their main tasks is to generate elaborate information, quite often in the form of key performance indicators (KPIs), with the purpose of facilitating the implementation of corrective actions.

ERP systems represent the top of the pyramid, corresponding to the enterprise business planning activities that allows assigning global targets to production scheduling. For many years, it has been considered to be out of the scope of the field of control, but nowadays, more and more, supply chain management is viewed and addressed as a control and optimization problem in research.


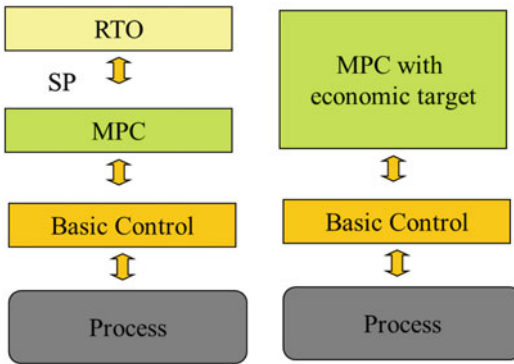
Control Hierarchy of Large Processing Plants: An Overview, Fig. 5 Two possible implementations of RTO

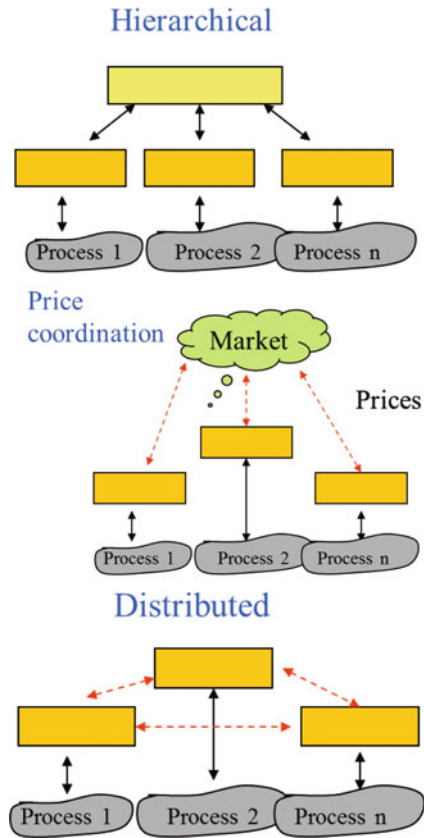
Future Control and Optimization at Plant Scale

Going back to Fig. 1, the variety of control and optimization problems increases as we move up in the control hierarchy, entering the field of dynamic process operations and considering not only individual process units but also larger sets of equipment or whole plants. Examples at the RTO (or MES) level are optimal management of shared resources or utilities, production bottleneck avoidance, optimal energy use or maximum efficiency, smooth transitions against production changes, etc.

Above, we have mentioned RTO as the most common approach for plant-wide optimization. Normally, RTO systems perform the optimization of an economic cost function using a nonlinear

process model in steady state and the corresponding operational constraints to generate targets for the control systems on the lower layers. The implementation of RTO provides consistent benefits by looking at the optimal operation problem from a plant-wide perspective. Nevertheless, in practice, when MPCs with local optimizers are operating the process units, many coordination problems appear between these layers, due to differences in models and targets, so that driving the operation of these process units in a coherent way with the global economic targets is an additional challenge.

A different perspective is taken by the so-called self-optimizing control (Fig. 5 right, Skogestad 2000) that, instead of implementing the RTO solution online, uses it to design a control structure that assures a near optimum




Control Hierarchy of Large Processing Plants: An Overview, Fig. 6 Direct dynamic optimization

operation if some specially chosen variables are maintained closed to their targets.

As in any model-based approach, the problem of how to implement or modify the theoretical optimum computed by RTO so that the optimum computed with the model and the real optimum of the process coincide in spite of model errors, disturbances, etc., emerges. A common choice to deal with this problem is to update periodically the model using parameter estimation methods or data reconciliation with plant data in steady state. Also, uncertainty can be explicitly taken into account by considering different scenarios and optimizing the worst case, but this is conservative and does not take advantage of the plant measurements. Along this line, there are proposals of other solutions such as modifier-adaptation methods that use a fixed model and process measurements to modify the optimization problem so that the final result corresponds to the process optimum (Marchetti et al. 2009) or the use of stochastic optimization where several scenarios are taken into account and future decisions are used as recourse variables (Lucia et al. 2013).

RTO is formulated in steady state, but in practice, most of the time the plants are in transients, and there are many problems, such as start-up optimization, that require a dynamic formulation. A natural evolution in this direction is to combine nonlinear MPC with economic optimization so that the target of the NMPC is not set point following but direct economic optimization as in the right-hand side of Fig. 6: ▸ Economic Model

Control Hierarchy of Large Processing Plants: An Overview, Fig. 7 Hierarchical, price coordination, and distributed approaches

Predictive Control and ▸ Model-Based Performance Optimizing Control (Engell 2007).

The type of problems that can be formulated within this framework is very wide, as are the possible fields of application. Processes with distributed parameter structure or mixtures of real and on/off variables, batch and continuous units, statistical distribution of particle sizes or properties, etc., give rise to special type of NMPC problems (see, e.g., Lunze and Lamnabhi-Lagarrigue 2009), but a common characteristic of all of them is the fact that they are computational intensive and should be solved taking into account the different forms of uncertainty always present.

Control and optimization are nowadays inseparable essential parts of any advanced approach to dynamic process operation. Progress in the field and spreading of the

industrial applications are possible thanks to the advances in optimization methods and tools and computing power available on the plant level, but implementation is still a challenge from many points of view, not only technical. Few suppliers offer commercial products, and finding optimal operation policies for a whole factory is a complex task that requires taking into consideration many aspects and elaborate information not available directly as process measurements. Solving large NMPC problems in real time may require breaking the associated optimization problem in subproblems that can be solved in parallel. This leads to several local controllers/optimizers, each one solving one subproblem involving variables of a part of the process and linked by some type of coordination. This offers a new point of view of the control hierarchy. Typically, three types of architectures are mentioned for dealing with this problem, represented in Fig. 7: In the hierarchical approach, coordination between local controllers is made by an upper layer that deals with the interactions, assigning targets to them. In price coordination, the coordination task is performed by a market-like mechanism that assigns different prices to the cost functions of every local controller/optimizer. Finally, in the distributed approach, the local controllers coordinate their actions by interchanging information about its decisions or states with neighbors (Scattolini 2009).

Summary and Future Research

Process control is a key element in the operation of process plants. At the lowest layer, it can be considered a mature, well-proven technology, even if many problems such as control structure selection and controller tuning in reality are often not solved well. The range of problems under consideration is continuously expanding to the upper layers of the hierarchy, merging control with process operation and optimization, creating new challenges that range from modeling and estimation to efficient large-scale optimization

and robustness against uncertainty, and leading to new challenges and problems for research and possibly large improvements of plant operations.

Control of Biotechnological Processes

Rudibert King
Technische Universität Berlin, Berlin, Germany

Abstract

Closed-loop control can significantly improve the performance of bioprocesses, e.g., by an increase of the production rate of a target molecule or by guaranteeing reproducibility of the production with low variability. In contrast to the control of chemical reaction systems, the biological reactions take place inside cells which constitute highly regulated, i.e., internally controlled systems by themselves. As a result, through evolution, the same cell can and will mimic a system of first order in some situations and a high-dimensional, highly nonlinear system in others. A complete mathematical description of the possible behaviors of the cell is still beyond reach and would be far too complicated as a basis for model-based process control. This makes supervision, control, and optimization of biosystems very demanding.

Keywords

Bioprocess control; Control of uncertain systems; Optimal control; Parameter identification; State estimation; Structure identification; Structured models

Introduction

Biotechnology offers solutions to a broad spectrum of challenges faced today, e.g., for health care, remediation of environmental pollution, new sources for energy supplies, sustainable food production, and the supply of bulk chemicals. To explain the needs for control of bioprocesses, especially for the production of high-value and/or large-volume compounds, it is instructive to have a look on the development of a new process. If a potential strain is found or genetically engineered, the biologist will determine favorable environmental factors for the growth of and the production of the target product by the cells. These factors typically comprise the levels of temperature, pH, dissolved oxygen, etc. Moreover, concentration regions for the nutrients, precursors, and so-called trace elements are specified. Whereas for the former variables often "optimal" setpoints are provided which, at least in smaller scale reactors, can be easily maintained by independent classically designed controllers, information about the best nutrient supply is incomplete from a control engineering point of view. It is this dynamic nutrient supply which is most often not revealed in the biological laboratory and which, however, offers substantial room for production improvements by control.

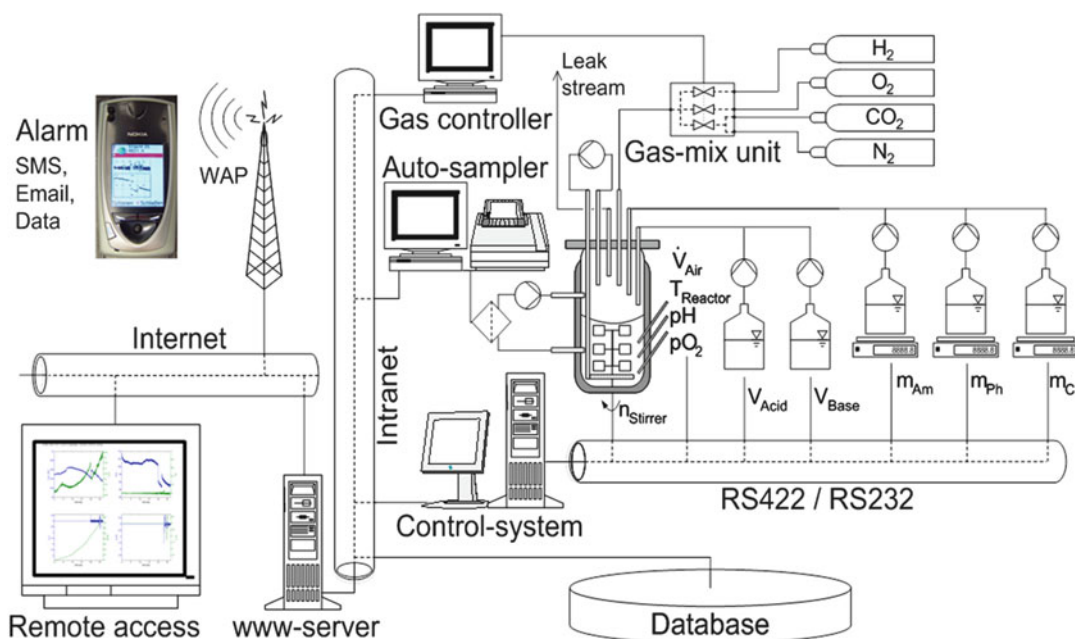
Irrespective whether bacteria, yeasts, fungi, or animal cells are used for production, these cells will consist of thousands of different compounds which react with each other in hundreds or more reactions. All reactions are tightly regulated on a molecular and genetic basis; see ▶ Deterministic Description of Biochemical Networks. For so-called unlimited growth conditions, all cellular compartments will be built up with the same specific growth rate, meaning that the cellular composition will not change over time. In a mathematical model describing growth and production, only one state variable will be needed to describe the biotic phase. This will give rise to unstructured models; see below. Whenever a cell enters a limitation, which is often needed for production, the cell will start to reorganize its internal reaction pathways. Model-based approaches of supervision and control based on unstructured models are now bound to fail. More biotic state variables are needed. However, it is not clear which and how many. As a result, modeling of limiting behaviors is challenging and crucial for the control of biotechnological processes. It requires a large amount of process-specific information. Moreover, model-based estimates of

the state of the cell and of the environment are a key factor as online measurements of the internal processes in the cell and of the nutrient concentrations are usually impossible. Finally, as models used for process control have to be limited in size and thus only give an approximative description, robustness of the methods has to be addressed.

Mathematical Models

For the production of biotechnical goods, many up- and downstream unit operations are involved besides the biological reactions. As these pose no typical bio-related challenges, we will concentrate here on the cultivation of the organisms only. This is mostly performed in aqueous solutions in special bioreactors through which air is sparged for a supply with oxygen. In some cases, other gases are supplied as well; see Fig. 1. Disregarding wastewater treatment plants, most cultivations are still performed in a fed-batch mode, meaning that a small amount of cells and part of the nutrients are put into the reactor initially. Then more nutrients and correcting fluids, e.g.,

for pH or antifoam control, are added with variable rates leading to an unsteady behavior. The system to be modeled consists of the gaseous, the liquid, and the biotic phase inside the reactor. For the former ones, balance equations can be formulated readily. The biotic phase can be modeled in a structured or unstructured way. Moreover, as not all cells behave similarly, this may give rise to a segregated model formulation which is omitted here for brevity.

Unstructured Models
If the biotic phase is represented by just one state variable, m_X, a typical example of a simple unstructured model of the liquid phase would be


$$\dot{m}_X = \mu_X m_X$$
$$\dot{m}_P = \mu_P m_X$$
$$\dot{m}_S = -a_1 \mu_X m_X - a_2 \mu_P m_X + c_{S,feed} u$$
$$\dot{m}_O = a_3(a_4 - c_O) - a_5 \mu_X m_X - a_6 \mu_P m_X$$
$$\dot{V} = u$$

Control of Biotechnological Processes, Fig. 1 Modern laboratory reactor platform for control-oriented process development

Control of Biotechnological Processes, Table 1 Multiplicative rates depending on several concentrations $c_1, \ldots, c_k$ with possible kinetic terms

$\mu_i = a_{imax}\mu_{i1}(c_1) \cdot \mu_{i2}(c_2) \cdot \ldots \cdot \mu_{ik}(c_k)$		
μ_{ij}		
$\dfrac{c_j}{c_j + a_{ij}}$	$\dfrac{a_{ij}}{c_j + a_{ij}}$	$\dfrac{c_j}{c_j^2 + a_{ij}}$
$\dfrac{c_j}{c_j + a_{ij}}e^{-c_j/a_{ij+1}}$	$\dfrac{c_j}{a_{ij}c_j^2 + c_j + a_{ij+1}}$	$\ldots$

with the masses m_i with $i = X, P, S, O$ for cells, product, substrate or nutrient, and dissolved oxygen, respectively. The volume is given by V, and the specific growth and production rates μ_X and μ_P depend on concentrations $c_i = m_i/V$, e.g., of the substrate S or oxygen O according to formal kinetics, e.g.,

$$\mu_X = \frac{a_7 c_S c_O}{(c_S + a_8)(c_O + a_9)}$$
$$\mu_P = \frac{a_{10} c_S}{a_{11} c_S^2 + c_S + a_{12}}$$

The nutrient supply can be changed by the feed rate $u(t)$ as a control input, with inflow concentration $c_{S,feed}$. Very often, just one feed stream is considered in unstructured models. As all parameters a_i have to be identified from noisy and infrequently sampled data, a low-dimensional nonlinear uncertain model results. All steps prior to the cultivation in which, e.g., from frozen cells, enough cells are produced to start the fermentation add to the uncertainty. Whereas the balance equations follow from first principles-based modeling, the structure of the kinetics μ_X and μ_P is unknown, i.e., empirical relations are exploited. Many different kinetic expressions can be used here; see Bastin and Dochain (1990) or a small selection shown in Table 1.

It has to be pointed out that, most often, neither c_X, c_P, nor c_S are measured online. As the measurement of c_O might be unreliable, the exhaust gas concentration of the gaseous phase is the main online measurement which can be used by employing an additional balance equation for the gaseous phase. Infrequent at-line measurements, though, are sometimes available for X, P, S, especially at the lab-scale during process development.

Structured Models

In structured models, the changing composition and reaction pathways of the cell is accounted for. As detailed information about the cell's complete metabolism including all regulations is missing for the majority if not all cells exploited in bioprocesses, an approximative description is used. Examples are models in which a part of the real metabolism is described on a mechanistic level, whereas the rest is lumped together into one or very few states (Goudar et al. 2006), cybernetic models (Varner and Ramkrishna 1998), or compartment models (King 1997). As an example, all compartment models can be written down as

$$\underline{\dot{m}} = \mathbf{A}\underline{\mu}(\underline{c}) + \underline{f}_{in}(\underline{u}) + \underline{f}_{out}(\underline{u})$$
$$\dot{V} = \sum_i u_i$$

with vectors of streams into and out of the reaction mixture, $\underline{f}_{in}$ and $\underline{f}_{out}$, which depend on control inputs $\underline{u}$; a matrix of (stoichiometric) parameters, $\mathbf{A}$; a vector of reaction rates $\underline{\mu} = \underline{\mu}(\underline{c})$; and, finally, a vector $\underline{m}$ comprising substrates, products, and more than one biotic state. These biotic states can be motivated, for example, by physiological arguments, describing the total amounts of macromolecules in the cell, such as the main building blocks DNA, RNA, and proteins. In very simple compartment models, the cell is only divided up into what is called active and inactive biomass. Again, all coefficients in $\mathbf{A}$ and the structure and the coefficients of all entries in $\underline{\mu}(\underline{c})$ (see Table 1) are unknown and have to be identified based on experimental data. Issues of structural and practical identifiability are of major concern. For models of system biology (see ▶ Deterministic Description of Biochemical Networks), algebraic equations are

added that describe the dependencies between individual fluxes. Then at least part of **A** is known.

Describing the biotic phase with a higher degree of granularity does not change the measurement situation in the laboratory or in the production scale, i.e., still only very few online measurements will be available for control.

Identification

Even if the growth medium initially "only" consists of some 10–20 different, chemically well-defined substances, from which only few are described in the model, this situation will change over the cultivation time as the organisms release further compounds from which only few may be known. If, for economic reasons, complex raw materials are used, even the initial composition is unknown. Hence, measuring the concentrations of some of the compounds of the large set of substances as a basis for modeling is not trivial. For structured models, intracellular substances have to be determined additionally. These are embedded in an even larger matrix of compounds making chemical analysis more difficult. Therefore, the basis for parameter and structure identification is uncertain.

As the expensive experiments and chemical analysis tasks are very time consuming, sometimes lasting up to several weeks, methods of optimal experimental design should always be considered in biotechnology; see ▶ Experiment Design and Identification for Control.

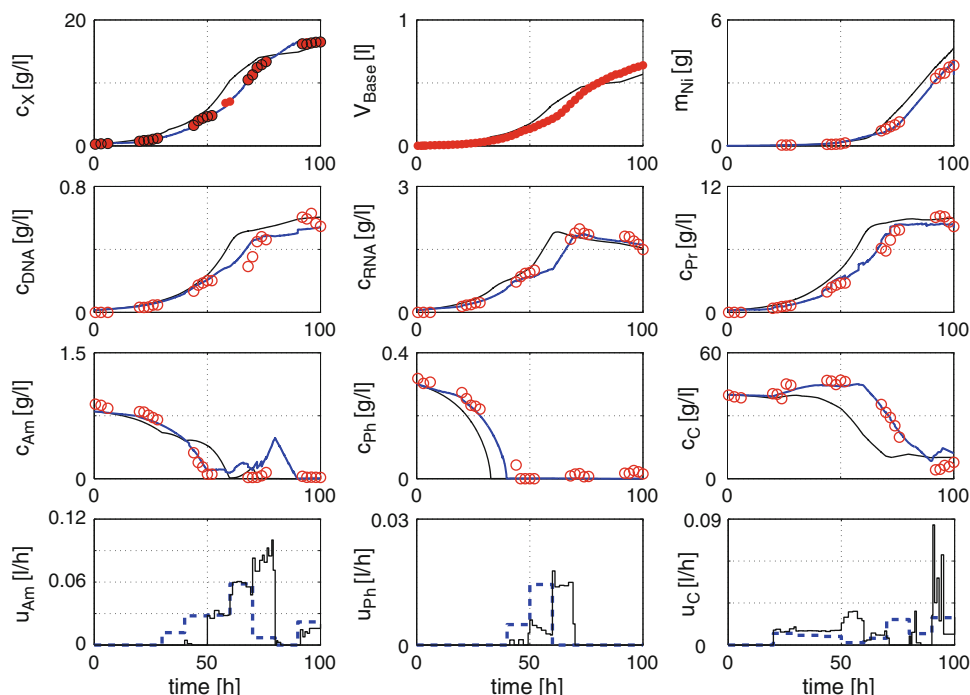
The models to be built up should possess some predictive capability for a limited range of environmental conditions. This rules out unstructured models for many practical situations. However, for process control, the models should still be of manageable complexity. Medium-sized structured models seem to be well suited for such a situation. The choice of biotic states in $\underline{m}$ and possible structures for the reaction rates μ_i, however, is hardly supported by biological or chemical evidence. As a result, a combined structure and parameter identification problem has to be solved. The choices of possible terms μ_{ij} in all μ_i give rise to a problem that exhibits

a combinatorial explosion. Although approaches exist to support this modeling step (see Herold and King 2013 or Mangold et al. 2005) finally, the modeler will have to settle with a compromise with respect to the accuracy of the model found versus the number of fully identified model candidates. As a result, all control methods applied should be robust in some sense.

Soft Sensors

Despite many advantages in the development of online measurements (see Mandenius and Titchener-Hooker 2013) systems for supervision and control of biotechnical processes often include model-based estimations schemes, such as extended Kalman filters (EKF); see ▶ Kalman Filters. Concentration estimates are needed for unmeasured substances and for quantities which depend on these concentrations like the growth rate of the cells. In real applications, formulations have to be used which account for delays in laboratory analysis of up to several hours and for situations in which results from the laboratory will not be available in the same sequence as the samples were taken. An example from a real cultivation is shown in Fig. 2. Here, the at-line measurement of the biomass concentration, $c_X = m_X / V$, is the only measurement available. The result of a single measurement is obtained about 30 min after sampling. For reference, unaccessible state variables, which were analyzed later, are shown as well along with the online estimates. The scatter of the data, especially of DNA and RNA, gives a qualitative impression of the measurement accuracy in biotechnology.

Control

Beside the relatively simple control of physical parameters, such as temperature, pH, dissolved oxygen, or carbon dioxide concentration, only few biotic variables are typically controlled with respect to a setpoint. The most prominent example is the growth rate of the biomass with the goal to reach a high cell concentration


Control of Biotechnological Processes, Fig. 2 Estimation of states of a structured model with an EKF with an unexpected growth delay initially. At-line measurement m_X (*red filled circles*), initially predicted evolution of states (*black*), online estimated evolution (*blue*), off-line data analyzed after the experiment (*open red circles*) (Data obtained by T. Heine)

in the reactor as fast as possible. This is the predominant goal when the cells are the primary target as in baker's yeast cultivations or when the expression of the desired product is growth associated. For other non-growth-associated products, a high cell mass is desirable as well, as production is proportional to the amount of cells. If the nutrient supply is maintained above a certain level, unlimited growth behavior results, allowing the use of unstructured models for model-based control. An excess of nutrients has to be avoided, though, as some organisms, like baker's yeast, will initiate an overflow metabolism, with products which may be inhibitory in later stages of the cultivation. For some products, such as the antibiotic penicillin, the organism has to grow slowly to obtain a high production rate. For these so-called secondary metabolites, low but not vanishing concentrations for some limiting substrates are needed. If setpoints are given for these

concentrations instead, this can pose a rather challenging control problem. As the organisms try to grow exponentially, the controller must be able to increase the feed exponentially as well. The difficulty mainly arises from the inaccurate and infrequent measurements that the soft sensors/controller has to work with and from the danger that an intermediate shortage or oversupply with nutrients may switch the metabolism to an undesired state of low productivity.

For control of biotechnical processes, many methods explained in this encyclopedia including feedforward, feedback, model-based, optimal, adaptive, fuzzy, neural nets, etc., can be and have been used (cf. Dochain 2008; Gnoth et al. 2008; Rani and Rao 1999). As in other areas of application, (robust) model-predictive control schemes (MPC) (see ▶ Industrial MPC of Continuous Processes) are applied with great success in biotechnology.

Control of Biotechnological Processes, Fig. 3 MPC control and state estimation of a cultivation with *S. tendae*. At-line measurement m_X (*red filled circles*), initially predicted evolution of states (*black*), online estimated evolution (*blue*), off-line data analyzed after the experiment (*open red circles*). Off-line optimal feeding profiles u_i (*blue broken line*), MPC-calculated feeds (*black, solid*) (Data obtained by T. Heine)

For the antibiotic production shown in Fig. 3, optimal feeding profiles u_i for ammonia (AM), phosphate (PH), and glucose (C) were calculated before the experiment was performed in a trajectory optimization such that the final mass of the desired antibiotic nikkomycin (Ni) was maximized. This resulted in the blue broken lines for the feeds u_i. However, due to disturbances and model inaccuracies, an MPC scheme had to significantly change the feeding profiles, to actually obtain this high amount of nikkomycin; see the feeding profiles given in black solid lines. This example shows that, especially in biotechnology, off-line trajectory planning has to be complemented by closed-loop concepts.

On the other hand, the experimental data given in Fig. 2 shows that significant disturbances, such as an unexpected initial growth delay, may occur in real systems as well. For this reason, the classical receding horizon MPC with an off-line determined optimal reference trajectory will not always be the best solution, and an online optimization over the whole horizon has a larger potential (cf. Kawohl et al. 2007).

Summary and Future Directions

Advanced process control including soft sensors can significantly improve biotechnical processes. Using these techniques promotes quality and reproducibility of processes (Junker and Wang 2006). These methods should, however, not only be exploited in the production scale. For new pharmaceutical products, the time to market is the decisive factor. Methods of (model-based) monitoring and control can help here to speed up process development. Since a few years, a clear trend can be seen in biotechnology to miniaturize and parallelize process development using multi-fermenter systems and robotic tech-

nologies. This trend gives rise to new challenges for modeling on the basis of huge data sets and for control in very small scales. At the same time, it is expected that a continued increase of information from bioinformatic tools will be available which has to be utilized for process control as well. Going to large-scale cultivations adds further spatial dimensions to the problem. Now, the assumption of a well-stirred, ideally mixed reactor does not longer hold. Substrate concentrations will be space dependent. Cells will experience changing good and bad nutrient environments frequently. Thus, mass transfer has to be accounted for, leading to partial differential equations as models for the process.

Control of Fluids and Fluid-Structure Interactions

Jean-Pierre Raymond
Institut de Mathématiques, Université Paul Sabatier Toulouse III & CNRS, Toulouse Cedex, France

Abstract

We introduce control and stabilization issues for fluid flows along with known results in the field. Some models coupling fluid flow equations and equations for rigid or elastic bodies are presented, together with a few controllability and stabilization results.

Keywords

Control; Fluid flows; Fluid-structure systems; Stabilization

Some Fluid Models

We consider a fluid flow occupying a bounded domain $\Omega_F \subset \mathbb{R}^N$, with $N = 2$ or $N = 3$, at the initial time $t = 0$, and a domain $\Omega_F(t)$

at time $t > 0$. Let us denote by $\rho(x, t) \in \mathbb{R}^+$ the density of the fluid at time t at the point $x \in \Omega_F(t)$ and by $u(x, t) \in \mathbb{R}^N$ its velocity. The fluid flow equations are derived by writing the mass conservation

$$\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho u) = 0 \quad \text{in } \Omega_F(t), \quad \text{for } t > 0, \ (1)$$

and the balance of momentum

$$\rho\left(\frac{\partial u}{\partial t} + (u \cdot \nabla)u\right) = \operatorname{div}\sigma + \rho\, f \qquad (2)$$
$$\text{in } \Omega_F(t), \quad \text{for } t > 0$$

where σ is the so-called constraint tensor and f represents a volumic force. For an isothermal fluid, there is no need to complete the system by the balance of energy. The physical nature of the fluid flow is taken into account in the choice of the constraint tensor σ. When the volume is preserved by the fluid flow transport, the fluid is called incompressible. The incompressibility condition reads as $\operatorname{div} u = 0$ in $\Omega_F(t)$. The incompressible Navier-Stokes equations are the classical model to describe the evolution of isothermal incompressible and Newtonian fluid flows. When in addition the density of the fluid is assumed to be constant, $\rho(x, t) = \rho_0$, the equations reduce to

$$\operatorname{div} u = 0,$$
$$\rho_0\left(\frac{\partial u}{\partial t} + (u \cdot \nabla)u\right) = \nu\Delta u - \nabla p + \rho_0\, f$$
$$\text{in } \Omega_F(t), \quad t > 0, \qquad (3)$$

which are obtained by setting

$$\sigma = \nu\left(\nabla u + (\nabla u)^T\right) + \left(\mu - \frac{2\nu}{3}\right)\operatorname{div} u\, I - pI, \qquad (4)$$

in Eq. (2). When $\operatorname{div} u = 0$, the expression of σ simplifies. The coefficients $\nu > 0$ and $\mu > 0$ are the viscosity coefficients of the fluid, and $p(x, t)$ its pressure at the point $x \in \Omega_F(t)$ and at time $t > 0$.

This model has to be completed with boundary conditions on $\partial\Omega_F(t)$ and an initial condition at time $t = 0$.

The incompressible Euler equations with constant density are obtained by setting $\nu = 0$ in the above system.

The compressible Navier-Stokes system is obtained by coupling the equation of conservation of mass Eq. (1) with the balance of momentum Eq. (2), where the tensor σ is defined by Eq. (4), and by completing the system with a constitutive law for the pressure.

Control Issues

There are unstable steady states of the Navier-Stokes equations which give rise to interesting control problems (e.g., to maximize the ratio "lift over drag"), but which cannot be observed in real life because of their unstable nature. In such situations, we would like to maintain the physical model close to an unstable steady state by the action of a control expressed in feedback form, that is, as a function either depending on an estimation of the velocity or depending on the velocity itself. The estimation of the velocity of the fluid may be recovered by using some real-time measurements. In that case, we speak of a feedback stabilization problem with partial information. Otherwise, when the control is expressed in terms of the velocity itself, we speak of a feedback stabilization problem with full information.

Another interesting issue is to maintain a fluid flow (described by the Navier-Stokes equations) in the neighborhood of a nominal trajectory (not necessarily a steady state) in the presence of perturbations. This is a much more complicated issue which is not yet solved.

In the case of a perturbation in the initial condition of the system (the initial condition at time $t = 0$ is different from the nominal velocity held at time $t = 0$), the exact controllability to the nominal trajectory consists in looking for controls driving the system in finite time to the desired trajectory.

Thus, control issues for fluid flows are those encountered in other fields. However there are

specific difficulties which make the corresponding problems challenging. When we deal with the incompressible Navier-Stokes system, the pressure plays the role of a Lagrange multiplier associated with the incompressibility condition. Thus, we have to deal with an infinite-dimensional nonlinear differential algebraic system. In the case of a Dirichlet boundary control, the elimination of the pressure, by using the so-called Leray or Helmholtz projector, leads to an unusual form of the corresponding control operator; see Raymond (2006). In the case of an internal control, the estimation of the pressure to prove observability inequalities is also quite tricky; see Fernandez-Cara et al. (2004). From the numerical viewpoint, the approximation of feedback control laws leads to very large-size problems, and new strategies have to be found for tackling these issues.

Moreover, the issues that we have described for the incompressible Navier-Stokes equations may be studied for other models like the compressible Navier-Stokes equations, the Euler equations (describing nonviscous fluid flows) both for compressible and incompressible models, or even more complicated models.

Feedback Stabilization of Fluid Flows

Let us now describe what are the known results for the incompressible Navier-Stokes equations in 2D or 3D bounded domains, with a control acting locally in a Dirichlet boundary condition. Let us consider a given steady state (u_s, p_s) satisfying the equation

$$-\nu \Delta u_s + (u_s \cdot \nabla) u_s + \nabla p_s = f_s,$$
$$\text{and} \quad \text{div } u_s = 0 \quad \text{in} \quad \Omega_F,$$

with some boundary conditions which may be of Dirichlet type or of mixed type (Dirichlet-Neumann-Navier type). For simplicity, we only deal with the case of Dirichlet boundary conditions

$$u_s = g_s \quad \text{on} \quad \partial \Omega_F,$$

where g_s and f_s are time-independent functions. In the case $\Omega_F(t) = \Omega_F$, not depending on t, the corresponding instationary model is

$$
\begin{aligned}
&\frac{\partial u}{\partial t} - \nu \Delta u + (u \cdot \nabla) u + \nabla p = f_s \\
&\text{and} \quad \text{div } u = 0 \text{ in } \Omega_F \times (0, \infty), \\
&u = g_s + \sum_{i=1}^{N_c} f_i(t) g_i, \ \partial \Omega_F \times (0, \infty) \\
&u(0) = u_0 \quad \text{on } \Omega_F.
\end{aligned}
\tag{5}
$$

In this model, we assume that $u_0 \neq u_s$, g_i are given functions with localized supports in $\partial \Omega_F$ and $f(t) = (f_1(t), \ldots, f_{N_c}(t))$ is a finite-dimensional control. Due to the incompressibility condition, the functions g_i have to satisfy

$$\int_{\partial \Omega_F} g_i \cdot n = 0,$$

where n is the unit normal to $\partial \Omega_F$, outward Ω_F.

The stabilization problem, with a prescribed decay rate $-\alpha < 0$, consists in looking for a control f in feedback form, that is, of the form

$$f(t) = K(u(t) - u_s), \tag{6}$$

such that the solution to the Navier-Stokes system Eq. (5), with f defined by Eq. (6), obeys

$$\left\| e^{\alpha t} (u(t) - u_s) \right\|_z \le \varphi \left(\|u_0 - u_s\|_z \right),$$

for some norm Z, provided $\|u_0 - u_s\|_z$ is small enough and where φ is a nondecreasing function. The mapping K, called the feedback gain, may be chosen linear.

The usual procedure to solve this stabilization problem consists in writing the system satisfied by $u - u_s$, in linearizing this system, and in looking for a feedback control stabilizing this linearized model. The issue is first to study the stabilizability of the linearized model and, when it is stabilizable, to find a stabilizing feedback gain. Among the feedback gains that stabilize the linearized model, we have to find one able to stabilize, at least locally, the nonlinear system too.

The linearized controlled system associated with Eq. (5) is

$$\frac{\partial v}{\partial t} - \nu \Delta v + (u_s \cdot \nabla)v + (v \cdot \nabla)u_s + \nabla q = 0$$
and   div $v = 0$ in $\Omega_F \times (0, \infty)$,
$v = \sum_{i=1}^{N_c} f_i(t)g_i$ on $\partial\Omega_F \times (0, \infty)$,
$v(0) = v_0$ on Ω_F.
(7)

The easiest way for proving the stabilizability of the controlled system Eq. (7) is to verify the Hautus criterion. It consists in proving the following unique continuation result. If $(\phi_j, \psi_j, \lambda_j)$ is the solution to the eigenvalue problem

$$\lambda_j \phi_j - \nu \Delta \phi_j - (u_s \cdot \nabla)\phi_j + (\nabla u_s)^T \phi_j$$
$$+ \nabla \psi_j = 0 \quad \text{and} \quad \text{div} \phi_j = 0 \text{ in } \Omega_F,$$
$$\phi_j = 0 \text{ on } \partial\Omega_F, \quad \text{Re } \lambda_j \geq -\alpha, \quad (8)$$

and if in addition (ϕ_j, ψ_j) satisfies

$$\int_{\partial\Omega_F} g_i \cdot \sigma(\phi_j, \psi_j)n = 0 \quad \text{for all } 1 \leq i \leq N_c,$$

then $(\phi_j, \psi_j) = 0$. By using a unique continuation theorem due to Fabre and Lebeau (1996), we can explicitly determine the functions g_i so that this condition is satisfied; see Raymond and Thevenet (2010). For feedback stabilization results of the Navier-Stokes equations in two or three dimensions, we refer to Fursikov (2004), Raymond (2006), Barbu et al. (2006), Raymond (2007), Badra (2009), and Vazquez and Krstic (2008).

Controllability to Trajectories of Fluid Flows

If $(\tilde{u}(t), \tilde{p}(t))_{0 \leq t < \infty}$ is a solution to the Navier-Stokes system, the controllability problem to the trajectory $(\tilde{u}(t), \tilde{p}(t))_{0 \leq t < \infty}$, in time $T > 0$, may be rewritten as a null controllability problem satisfied by $(v, q) = (u - \tilde{u}, p - \tilde{p})$. The local null controllability in time $T > 0$ follows from the null controllability of the linearized system and from a fixed point argument. The linearized controlled system is

$$\frac{\partial v}{\partial t} - \nu \Delta v + (\tilde{u}(t) \cdot \nabla)v + (v \cdot \nabla)\tilde{u}(t) + \nabla q = 0$$
and   div $v = 0$ in $\Omega_F \times (0, T)$,
$v = m_c f$ on $\partial\Omega_F \times (0, T)$,
$v(0) = v_0 \in L^2(\Omega_F; \mathbb{R}^N)$,   div $v_0 = 0$.
(9)

The nonnegative function m_c is used to localize the boundary control f. The control f is assumed to satisfy

$$\int_{\partial\Omega_F} m_c f \cdot n = 0. \quad (10)$$

As for general linear dynamical systems, the null controllability of the linearized system follows from an observability inequality for the solutions to the following adjoint system

$$-\frac{\partial \phi}{\partial t} - \nu \Delta \phi - (\tilde{u}(t) \cdot \nabla)\phi + (\nabla \tilde{u}(t))^T \phi + \nabla \psi = 0$$
and div $\phi = 0$ in $\Omega_F \times (0, T)$,
$\phi = 0$ on $\partial\Omega_F \times (0, T)$,
$\phi(T) \in L^2(\Omega_F; \mathbb{R}^N)$,   div $\phi(T) = 0$.
(11)

Contrary to the stabilization problem, the null controllability by a control of finite dimension seems to be out of reach and it will be impossible in general. We look for a control $f \in L^2(\partial\Omega_F; \mathbb{R}^N)$, satisfying Eq. (10), driving the solution to system Eq. (9) in time T to zero, that is, such that the solution $v_{v_0, f}$ obeys $v_{v_0, f}(T) = 0$. The linearized system Eq. (9) is null controllable in time $T > 0$ by a boundary control $f \in L^2(\partial\Omega_F; \mathbb{R}^N)$ obeying Eq. (10), if and only if there exists $C > 0$ such that

$$\int_{\Omega_F} |\phi(0)|^2 \, dx \leq C \int_{\partial\Omega_F} m_c |\sigma(\phi, \psi)n|^2 \, dx, \quad (12)$$

for all solution (ϕ, ψ) of Eq. (11). The observability inequality Eq. (12) may be proved by establishing weighted energy estimates called "Carleman-type estimates"; see Fernandez-Cara et al. (2004) and Fursikov and Imanuvilov (1996).

Additional Controllability Results for Other Fluid Flow Models

The null controllability of the 2D incompressible Euler equation has been obtained by J.-M. Coron with the so-called Return Method (Coron 1996). See also Coron (2007) for additional references (in particular, the 3D case has been treated by O. Glass).

Some null controllability results for the one-dimensional compressible Navier-Stokes equations have been obtained in Ervedoza et al. (2012).

Fluid-Structure Models

Fluid-structure models are obtained by coupling an equation describing the evolution of the fluid flow with an equation describing the evolution of the structure. The coupling comes from the balance of momentum and by writing that at the fluid-structure interface, the fluid velocity is equal to the displacement velocity of the structure.

The most important difficulty in studying those models comes from the fact that the domain occupied by the fluid at time t evolves and depends on the displacement of the structure. In addition, when the structure is deformable, its evolution is usually written in Lagrangian coordinates while fluid flows are usually described in Eulerian coordinates.

The structure may be a rigid or a deformable body immersed into the fluid. It may also be a deformable structure located at the boundary of the domain occupied by the fluid.

A Rigid Body Immersed in a Three-Dimensional Incompressible Viscous Fluid

In the case of a 3D rigid body $\Omega_S(t)$ immersed in a fluid flow occupying the domain $\Omega_F(t)$, the motion of the rigid body may be described by the position $h(t) \in \mathbb{R}^3$ of its center of mass and by a matrix of rotation $Q(t) \in \mathbb{R}^{3 \times 3}$.

The domain $\Omega_S(t)$ and the flow X_S associated with the motion of the structure obey

$$
\begin{aligned}
& X_S(y, t) = h(t) + Q(t)Q_0^{-1}(y - h(0)), \\
& \text{for } y \in \Omega_S(0) = \Omega_S, \\
& \Omega_S(t) = X_S(\Omega_S(0), t),
\end{aligned} \tag{13}
$$

and the matrix $Q(t)$ is related to the angular velocity $\omega : (0, T) \mapsto \mathbb{R}^3$, by the differential equation

$$
Q'(t) = \omega(t) \times Q(t), \quad Q(0) = Q_0. \tag{14}
$$

We consider the case when the fluid flow satisfies the incompressible Navier-Stokes system Eq. (3) in the domain $\Omega_F(t)$ corresponding to Fig. 1. Denoting by $J(t) \in \mathbb{R}^{3 \times 3}$ the tensor of inertia at time t, and by m the mass of the rigid body, the equations of the structure are obtained by writing the balance of linear and angular momenta

$$
\begin{aligned}
& mh'' = \int_{\partial \Omega_S(t)} \sigma(u, p)n \, dx, \\
& J\omega' = J\omega \times \omega + \int_{\partial \Omega_S(t)} (x - h) \times \sigma(u, p)n \, dx, \\
& h(0) = h_0, \ h'(0) = h_1, \ \omega(0) = \omega_0,
\end{aligned} \tag{15}
$$

where n is the normal to $\partial \Omega_S(t)$ outward $\Omega_F(t)$. The system Eqs. (3) and (13)–(15) has to be completed with boundary conditions. At the fluid-structure interface, the fluid velocity is equal to the displacement velocity of the rigid solid:

$$
u(x, t) = h'(t) + \omega(t) \times (x - h(t)), \tag{16}
$$

for all $x \in \partial \Omega_S(t), t > 0$. The exterior boundary of the fluid domain is assumed to be fixed
Control of Fluids and Fluid-Structure Interactions, Fig. 1

$\Gamma_e = \partial\Omega_F(t)\backslash\partial\Omega_S(t)$. The boundary condition on $\Gamma_e \times (0, T)$ may be of the form

$$u = m_c\, f \quad \text{on} \ \ \Gamma_e \times (0, \infty), \qquad (17)$$

with $\int_{\Gamma_e} m_c\, f \cdot n = 0$, f is a control, and m_c a localization function.

An Elastic Beam Located at the Boundary of a Two-Dimensional Domain Filled by an Incompressible Viscous Fluid

When the structure is described by an infinite-dimensional model (a partial differential equation or a system of p.d.e.), there are a few existence results for such systems and mainly existence of weak solutions (Chambolle et al. 2005). But for stabilization and control problems of nonlinear systems, we are usually interested in strong solutions. Let us describe a two-dimensional model in which a one-dimensional structure is located on a flat part $\Gamma_S = (0, L) \times \{y_0\}$ of the boundary of the reference configuration of the fluid domain Ω_F. We assume that the structure is a Euler-Bernoulli beam with or without damping. The displacement η of the structure in the direction normal to the boundary Γ_S is described by the partial differential equation

$$\eta_{tt} - b\eta_{xx} - c\eta_{txx} + a\eta_{xxxx} = F, \text{in } \Gamma_S \times (0, \infty),$$
$$\eta = 0 \quad \text{and} \quad \eta_x = 0 \ \text{on} \ \partial\Gamma_S \times (0, \infty),$$
$$\eta(0) = \eta_1^0 \quad \text{and} \quad \eta_t(0) = \eta_2^0 \ \text{in} \ \Gamma_S,$$
$$(18)$$

where η_x, η_{xx}, and η_{xxxx} stand for the first, the second, and the fourth derivative of η with respect to $x \in \Gamma_S$. The other derivatives are defined in a similar way. The coefficients b and c are nonnegative, and $a > 0$. The term $c\eta_{txx}$ is a structural damping term. At time t, the structure occupies the position $\Gamma_S(t) = \{(x, y) \,|\, x \in (0, L), \ y = y_0 + \eta(x, t)\}$. When Ω_F is a two-dimensional model, Γ_S is of dimension one, and $\partial\Gamma_S$ is reduced to the two extremities of Γ_S. The momentum balance is

obtained by writing that F in Eq. (18) is given by $F = -\sqrt{1 + \eta_x^2}\,\sigma(u, p)\tilde{n} \cdot n$, where $\tilde{n}(x, y)$ is the unit normal at $(x, y) \in \Gamma_S(t)$ to $\Gamma_S(t)$ outward $\Omega_F(t)$, and n is the unit normal to Γ_S outward $\Omega_F(0) = \Omega_F$. If in addition, a control f acts as a distributed control in the beam equation, we shall have

$$F = -\sqrt{1 + \eta_x^2}\,\sigma(u, p)\tilde{n} \cdot n + f \qquad (19)$$

The equality of velocities on $\Gamma_S(t)$ reads as

$$u(x, y_0 + \eta(x, t)) = (0, \eta_t(x, t)),$$
$$x \in (0, L), t > 0. \qquad (20)$$

Control of Fluid-Structure Models

To control or to stabilize fluid-structure models, the control may act either in the fluid equation or in the structure equation or in both equations. There are a very few controllability and stabilization results for systems coupling the incompressible Navier-Stokes system with a structure equation. We state below two of those results. Some other results are obtained for simplified one-dimensional models coupling the viscous Burgers equation coupled with the motion of a mass; see Badra and Takahashi (2013) and the references therein.

We also have to mention here recent papers on control problems for systems coupling quasi-stationary Stokes equations with the motion of deformable bodies, modeling microorganism swimmers at low Reynolds number; see Alouges et al. (2008).

## Null Controllability of the Navier-Stokes System Coupled with the Motion of a Rigid Body

The system coupling the incompressible Navier-Stokes system Eq. (3) in the domain drawn in Fig. 1, with the motion of a rigid body

described by Eqs. (13)–(16), with the boundary control Eq. (17) is null controllable locally in a neighborhood of 0. Before linearizing the system in a neighborhood of 0, the fluid equations have to be rewritten in Lagrangian coordinates, that is, in the cylindrical domain $\Omega_F \times (0, \infty)$. The linearized system is the Stokes system coupled with a system of ordinary differential equations. The proof of this null controllability result relies on a Carleman estimate for the adjoint system; see, e.g., Boulakia and Guerrero (2013).

Feedback Stabilization of the Navier-Stokes System Coupled with a Beam Equation

The system coupling the incompressible Navier-Stokes system Eq. (3) in the domain drawn in Fig. 2, with beam Eqs. (18)–(20), can be locally stabilized with any prescribed exponential decay rate $-\alpha < 0$, by a feedback control f acting in Eq. (18) via Eq. (19); see Raymond (2010). The proof consists in showing that the infinitesimal generator of the linearized model is an analytic semigroup (when $c > 0$), that its resolvent is compact, and that the Hautus criterion is satisfied.

When the control acts in the fluid equation, the system coupling Eq. (3) in the domain drawn in Fig. 2, with the beam Eqs. (18)–(20), can be stabilized when $c > 0$. To the best of our knowledge, there is no null controllability result for such systems, even with controls acting both in the structure and fluid equations. The case where the beam equation is approximated by a finite-dimensional model is studied in Lequeurre (2013).

Control of Linear Systems with Delays

Wim Michiels
KU Leuven, Leuven (Heverlee), Belgium

Abstract

The presence of time delays in dynamical systems may induce complex behavior, and this behavior is not always intuitive. Even if a system's equation is scalar, oscillations may occur. Time delays in control loops are usually associated with degradation of performance and robustness, but, at the same time, there are situations where time delays are used as controller parameters.

Keywords

Delay differential equations; Delays as controller parameters; Functional differential equation

Introduction

Time-delays are important components of many systems from engineering, economics, and the life sciences, due to the fact that the transfer of material, energy, and information is mostly not instantaneous. They appear, for instance, as computation and communication lags, they model transport phenomena and heredity, and they arise as feedback delays in control loops. An overview of applications, ranging from traffic flow control and lasers with phase-conjugate feedback, over (bio)chemical reactors and cancer modeling, to control of communication networks and control via networks, is included in Sipahi et al. (2011).

The aim of this contribution is to describe some fundamental properties of linear control systems subjected to time-delays and to outline principles behind analysis and synthesis methods. Throughout the text, the results will be illustrated by means of the scalar system

$$\dot{x}(t) = u(t - \tau), \tag{1}$$

which, controlled with instantaneous state feedback, $u(t) = -kx(t)$, leads to the closed-loop system

$$\dot{x}(t) = -kx(t - \tau). \tag{2}$$

Although this didactic example is extremely simple, we shall see that its dynamics are already very rich and shed a light on delay effects in control loops.

In some works, the analysis of (2) is called the *hot shower problem*, as it can be interpreted as a (over)simplified model for a human adjusting the temperature in a shower: $x(t)$ then denotes the difference between the water temperature and the desired temperature as felt by the person, the term $-kx(t)$ models the reaction of the person by further opening or closing taps, and the delay is due to the propagation with finite speed of the water in the ducts.

Basis Properties of Time-Delay Systems

Functional Differential Equation
We focus on a model for a time-delay system described by

$$\dot{x}(t) = A_0 x(t) + A_1 x(t - \tau), \quad x(t) \in \mathbb{R}^n. \tag{3}$$

This is an example of a *functional differential equation* (FDE) of *retarded type*. The term FDE stems from the property that the right-hand side can be interpreted as a functional evaluated at a piece of trajectory. The term retarded expresses that the right-hand side does not explicitly depend on $\dot{x}$.

As a first difference with an ordinary differential equation, the initial condition of (3) at $t = 0$ is a function ϕ from $[-\tau, 0]$ to $\mathbb{R}^n$. For all $\phi \in \mathcal{C}\left([-\tau, 0], \mathbb{R}^n\right)$, where $\mathcal{C}\left([-\tau, 0], \mathbb{R}^n\right)$ is the space of continuous functions mapping the interval $[-\tau, 0]$ into $\mathbb{R}^n$, a forward solution $x(\phi)$ exists and is uniquely defined. In Fig. 1, a solution of the scalar system (2) is shown.

The discontinuity in the derivative at $t = 0$ stems from $A_0\phi(0) + A_1\phi(-\tau) \neq \lim_{\theta \to 0}\dot{\phi}$. Due to the smoothing property of an integrator, however, at $t = n \in \mathbb{N}$, the discontinuity will only be present in the $(n + 1)$th derivative. This illustrates a second property of functional

differential equations of retarded type: solutions become smoother as time evolves. As a third major difference with ODEs, backward continuation of solutions is not always possible (Michiels and Niculescu 2007).

Reformulation in a First-Order Form

The state of system (3) at time t is the minimal information needed to continue the solution, which, once again, boils down to a function segment $x_t(\phi)$ where $x_t(\phi)(\theta) = x(t + \theta)$, $\theta \in [-\tau, 0]$ (in Fig. 1, the function x_t is shown in red for $t = 5$). This suggests that (3) can be reformulated as a standard ordinary differential equation over the infinite-dimensional space $\mathcal{C}([-\tau, 0], \mathbb{R}^n)$. This equation takes the form

$$\frac{d}{dt}z(t) = \mathcal{A}z(t), \; z(t) \in \mathcal{C}\left([-\tau, 0], \mathbb{R}^n\right) \quad (4)$$

where operator $\mathcal{A}$ is given by

$$\mathcal{D}(\mathcal{A}) = \left\{ \phi \in \mathcal{C}\left([-\tau_m, 0], \mathbb{R}^n\right) : \begin{array}{l} \dot{\phi} \in \mathcal{C}\left([-\tau_m, 0], \mathbb{R}^n\right) \\ \dot{\phi}(0) = A_0\phi(0) + A_1\phi(-\tau) \end{array} \right\},$$

$$\mathcal{A}\phi \qquad\qquad\qquad = \frac{d\phi}{d\theta}. \qquad\qquad\qquad (5)$$

The relation between solutions of (3) and (4) is given by $z(t)(\theta) = x(t + \theta)$, $\theta \in [-\tau, 0]$. Note that all system information is concentrated in the nonlocal boundary condition describing the domain of $\mathcal{A}$. The representation (4) is closely related to a description by an advection PDE with a nonlocal boundary condition (Krstic 2009).

Asymptotic Growth Rate of Solutions and Stability

The reformulation of (3) into the standard form (4) allows us to define stability notions and to generalize the stability theory for ordinary differential equations in a straightforward way, with the main change that the state space is $\mathcal{C}([-\tau, 0], \mathbb{R}^n)$. For example, the null solution of (3) is exponentially stable if and only if there exist constants $C > 0$ and $\gamma > 0$ such that

$$\forall \phi \in \mathcal{C}\left([-\tau_m, 0], \mathbb{R}^n\right) \|x_t(\phi)\|_s \leq Ce^{-\gamma t}\|\phi\|_s,$$

where $\|\cdot\|_s$ is the supremum norm and $\|\phi\|_s = \sup_{\theta \in [-\tau, 0]}\|\phi(\theta)\|_2$. As the system is linear,
Control of Linear Systems with Delays, Fig. 1 Solution of (2) for $\tau = 1, k = 1$, and initial condition $\phi \equiv 1$

asymptotic stability and exponential stability are equivalent. A direct generalization of Lyapunov's second method yields:

Theorem 1 *The null solution of linear system* (3) *is asymptotically stable if there exist a continuous functional* $V : \mathcal{C}([-\tau, 0], \mathbb{R}^n) \to \mathbb{R}$ *(a so-called Lyapunov-Krasovskii functional) and continuous nondecreasing functions* $u, v, w :$ $\mathbb{R}^+ \to \mathbb{R}^+$ *with*

$$u(0) = v(0) = w(0) = 0 \text{ and } u(s) > 0,$$
$$v(s) > 0, w(s) > \text{ for } s > 0,$$

such that for all $\phi \in \mathcal{C}([-\tau, 0], \mathbb{R}^n)$

$$u(\|\phi\|_s) \le V(\phi) \le v(\|\phi()\|_2),$$
$$\dot{V}(\phi) \le -w(\|\phi()\|_2),$$

where

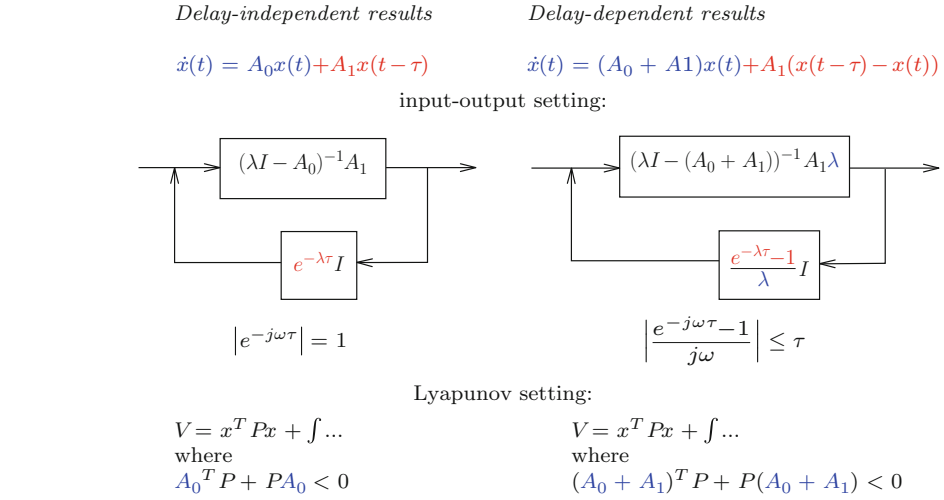
$$\dot{V}(\phi) = \lim_{h \to 0+} \sup \frac{1}{h}[V(x_h(\phi)) - V(\phi)].$$

Converse Lyapunov theorems and the construction of the so-called complete-type Lyapunov-Krasovskii functionals are discussed in Kharitonov (2013). Imposing a particular structure on the functional, e.g., a form depending only on a finite number of free parameters, often leads to easy-to-check stability criteria (for instance, in the form of LMIs), yet as price to pay, the obtained results may be conservative in the sense that the sufficient stability conditions might not be close to necessary conditions. As an alternative to Lyapunov functionals, Lyapunov functions can be used as well, provided that the condition $\dot{V} < 0$ is relaxed (the so-called Lyapunov-Razumikhin approach); see, for example, Gu et al. (2003).

Delay Differential Equations as Perturbation of ODEs

Many results on stability, robust stability, and control of time-delay systems are explicitly or implicitly based on a perturbation point of view, where delay differential equations are seen as perturbations of ordinary differential equations. For instance, in the literature, a classification of stability criteria is often presented in terms

of *delay-independent* criteria (conditions holding for all values of the delays) and *delay-dependent* criteria (usually holding for all delays smaller than a bound). This classification has its origin at two different ways of seeing (3) as a perturbation of an ODE, with as nominal system $\dot{x}(t) = A_0 x(t)$ and $\dot{x}(t) = (A_0 + A_1)x(t)$ (system for zero delay), respectively. This observation is illustrated in Fig. 2 for results based on input-output- and Lyapunov-based approaches.

The Spectrum of Linear Time-Delay Systems


Two Eigenvalue Problems

The substitution of an exponential solution in (3) leads us to the *nonlinear eigenvalue problem*

$$(\lambda I - A_0 - A_1 e^{-\lambda \tau})v = 0, \lambda \in \mathbb{C}, v \in \mathbb{C}^n, v \ne 0. \tag{6}$$

The solutions of the equation $\det(\lambda I - A_0 - A_1 e^{-\lambda \tau}) = 0$ are called characteristic roots. Similarly, formulation (4) leads to the equivalent *infinite-dimensional linear eigenvalue problem*

$$(\lambda I - \mathcal{A})u = 0, \lambda \in \mathbb{C}, u \in \mathcal{C}([-\tau, 0], \mathbb{C}^n), u \ne 0. \tag{7}$$

The combination of these two viewpoints lays at the basis of most methods for computing characteristic roots; see Michiels (2012). On the one hand, discretizing (7), i.e., approximating $\mathcal{A}$ with a matrix, and solving the resulting standard eigenvalue problems allow to obtain global information, for example, estimates of *all* characteristic roots in a given compact set or in a given right half plane. On the other hand, the (finitely many) nonlinear equations (6) allow to make *local corrections* on characteristic root approximations up to the desired accuracy, e.g., using Newton's method or inverse residual iteration. Linear time-delay systems satisfy spectrum-determined growth properties of solutions. For instance, the zero solution of (3) is asymptotically stable if and only if all characteristic roots are in the open left half plane.

Delay-independent results   *Delay-dependent results*

$$\dot{x}(t) = A_0 x(t) + A_1 x(t-\tau) \qquad \dot{x}(t) = (A_0 + A1)x(t) + A_1(x(t-\tau) - x(t))$$

input-output setting:

$$(\lambda I - A_0)^{-1} A_1 \qquad\qquad (\lambda I - (A_0 + A_1))^{-1} A_1 \lambda$$

$$e^{-\lambda\tau} I \qquad\qquad\qquad \frac{e^{-\lambda\tau} - 1}{\lambda} I$$

$$\left| e^{-j\omega\tau} \right| = 1 \qquad\qquad\qquad \left| \frac{e^{-j\omega\tau} - 1}{j\omega} \right| \le \tau$$

Lyapunov setting:

$$V = x^T P x + \int \dots \qquad\qquad V = x^T P x + \int \dots$$
where   where
$$A_0{}^T P + P A_0 < 0 \qquad\qquad (A_0 + A_1)^T P + P(A_0 + A_1) < 0$$

Control of Linear Systems with Delays, Fig. 2 The classification of stability criteria in delay-independent results and delay-dependent results stems from two different perturbation viewpoints. Here, perturbation terms are printed in *red*
Control of Linear Systems with Delays, Fig. 3 (*Left*) Rightmost characteristic roots of (2) for $k\tau = 1$. (*Right*) Real parts of rightmost characteristic roots as a function of $k\tau$

In Fig. 3 (left), the rightmost characteristic roots of (2) are depicted for $k\tau = 1$. Note that since the characteristic equation can be written as $\lambda\tau + k\tau e^{-\lambda\tau} = 0$, k and τ can be combined into one parameter. In Fig. 3 (right), we show the real parts of the characteristic roots as a function of $k\tau$. The plots illustrate some important spectral properties of retarded-type FDEs. First, even though there are in general infinitely many characteristic roots, the number of them in *any* right half plane is always finite. Second, the individual characteristic roots, as well as the *spectral*

abscissa, i.e., the supremum of the real parts of all characteristic roots, continuously depend on parameters. Related to this, a loss or gain of stability is always associated with characteristic roots crossing the imaginary axis. Figure 3 (right) also illustrates the transition to a delay-free system as $k\tau \to 0^+$.

Critical Delays: A Finite-Dimensional Characterization

Assume that for a given value of k, we are looking for values of the delay τ_c for which (2)

has a characteristic root $j\omega_c$ on the imaginary axis. From $j\omega = -ke^{-j\omega\tau}$, we get

$$\omega_c = k, \ \tau_c = \frac{\frac{\pi}{2} + l2\pi}{\omega_c}, \ l$$

$$= 0, 1, \ldots, \Re\left\{\frac{d\lambda}{d\tau}|_{(\tau_c, j\omega_c)}\right\}^{-1} = \frac{1}{\omega_c^2}. \quad (8)$$

Critical delay values τ_c are indicated with green circles on Fig. 3 (right). The above formulas first illustrate an *invariance property* of imaginary axis roots and their crossing direction with respect to delay shifts of $2\pi/\omega_c$. Second, the number of possible values of ω_c is one and thus *finite*. More generally, substituting $\lambda = j\omega$ in (6) and treating τ as a free parameter lead to a *two-parameter eigenvalue problem*

$$(j\omega I - A_0 - A_1 z)v = 0, \quad (9)$$

with ω on the real axis and $z := \exp(-j\omega\tau)$ on the unit circle. Most methods to solve such a problem boil down to an elimination of one of the independent variables ω or z. As an example of an elimination technique, we directly get from (9)

$$j\omega \in \sigma(A_0 + A_1 z), \ -j\omega \in \sigma(A_0^* + A_1^* z^{-1})$$

$$\Rightarrow \det\left((A_0 + A_1 z) \oplus (A_0^* + A_1^* z^{-1})\right) = 0,$$

where $\sigma(\cdot)$ denotes the spectrum and $\oplus$ the Kronecker sum. Clearly, the resulting eigenvalue problem in z is finite dimensional.

Control of Linear Time-Delay System

Limitations Induced by Delays

It is well known that delays in control loop may lead to a significant degradation of performance and robustness and even to instability (Niculescu 2001; Richard 2003). Let us return to example (2). As illustrated with Fig. 3 and expressions (8), the system loses stability if τ reaches the value $\pi/2k$, while stability cannot be recovered for larger delays. The maximum achievable exponential decay rate of the solutions, which corresponds to the minimum of the spectral abscissa, is given by $-1/\tau$; hence, large delays can only be tolerated at the price of a degradation of the rate of convergence. It should be noted that the limitations induced by delays are even more stringent if the uncontrolled systems are exponentially unstable, which is not the case for (2).

The analysis in the previous sections gives a hint why control is difficult in the presence of delays: the system is inherently infinite dimensional. As a consequence, most control design problems which involve determining a finite number of parameters can be interpreted as reduced-order control design problems or as control design problems for under-actuated systems, which both are known to be hard problems.

Fixed-Order Control

Most standard control design techniques lead to controllers whose dimension is larger or equal to the dimension of the system. For infinite-dimensional time-delay system, such controllers might have a disadvantage of being complicated and hard to implement. To see this, for a system with delay in the state, the generalization of static state feedback, $u(t) = k(x)$, is given by $u(t) = \int_{-\tau}^{0} x(t + \theta)d\mu(\theta)$, where μ is a function of bounded variation. However, in the context of large-scale systems, it is known that reduced-order controllers often perform relatively well compared to full-order controllers, while they are much easier to implement.

Recently, new methods for the design of controllers with a prescribed order (dimension) or structure have been proposed (Michiels 2012). These methods rely on a direct optimization of appropriately defined cost functions (spectral abscissa, $\mathcal{H}_2/\mathcal{H}_\infty$ criteria). While $\mathcal{H}_2$ criteria can be addressed within a derivative-based optimization framework, $\mathcal{H}_\infty$ criteria and the spectral abscissa require targeted methods for *non-smooth optimization problems*. To illustrate the need for such methods, consider again Fig. 3 (right): minimizing the spectral abscissa for a given value of τ as a function of the controller gain k leads to an optimum where the objective function is not differentiable, even not locally Lipschitz, as shown

by the red circle. In case of multiple controller parameters, the path of steepest descent in the parameter space typically has phases along a manifold characterized by the non-differentiability of the objective function.

Using Delays as Controller Parameters

In contrast to the detrimental effects of delays, there are situations where delays have a beneficial effect and are even used as controller parameters; see Sipahi et al. (2011). For instance, delayed feedback can be used to stabilize oscillatory systems where the delay serves to adjust the phase in the control loop. Delayed terms in control laws can also be used to approximate derivatives in the control action. Control laws which depend on the difference $x(t) - x(t - \tau)$, the so-called Pyragas-type feedback, have the property that the position of equilibria and the shape of periodic orbits with period τ are not affected, in contrary to their stability properties. Last but not least, delays can be used in control schemes to generate predictions or to stabilize predictors, which allow to compensate delays and improve performance (Krstic 2009; Zhong 2006). Let us illustrate the main idea once more with system (1).

System (1) has a special structure, in the sense that the delay is only in the input, and it is advantageous to exploit this structure in the context of control. Coming back to the didactic example, the person who is taking a shower is – possibly after some bad experiences – aware about the delay and will take into account his/her prediction of the system's reaction when adjusting the cold and hot water supply. Let us, to conclude, formalize this. The uncontrolled system can be rewritten as $\dot{x}(t) = v(t)$, where $v(t) = u(t - \tau)$. We know u up to the current time t; thus, we know v up to time $t + \tau$, and if $x(t)$ is also known, we can predict the value of x at time $t + \tau$,

$$x_p(t + \tau) = x(t) + \int_t^{t+\tau} v(s)ds$$
$$= x(t) + \int_{t-\tau}^t u(s)ds,$$

and use the predicted state for feedback. With the control law $u(t) = -kx_p(t + \tau)$, there is only one closed-loop characteristic root at $\lambda = -k$, i.e., as long as the model used in the predictor is exact, the delay in the loop is compensated by the prediction. For further reading on prediction-based controllers, see, e.g., Krstic (2009) and the references therein.

Conclusions

Time-delay systems, which appear in a large number of applications, are a class of infinite-dimensional systems, resulting in rich dynamics and challenges from a control point of view. The different representations and interpretations and, in particular, the combination of viewpoints lead to a wide variety of analysis and synthesis tools.

Control of Machining Processes

Kaan Erkorkmaz
Department of Mechanical & Mechatronics
Engineering, University of Waterloo, Waterloo,
ON, Canada

Abstract

Control of machining processes encompasses a broad range of technologies and innovations, ranging from optimized motion planning and servo drive loop design to on-the-fly regulation of cutting forces and power consumption to applying control strategies for damping out chatter vibrations caused by the interaction of the chip generation mechanism with the machine tool structural dynamics. This article provides a brief introduction to some of the concepts and technologies associated with machining process control.

Keywords

Adaptive control; Chatter vibrations; Feed drive control; Machining; Trajectory planning

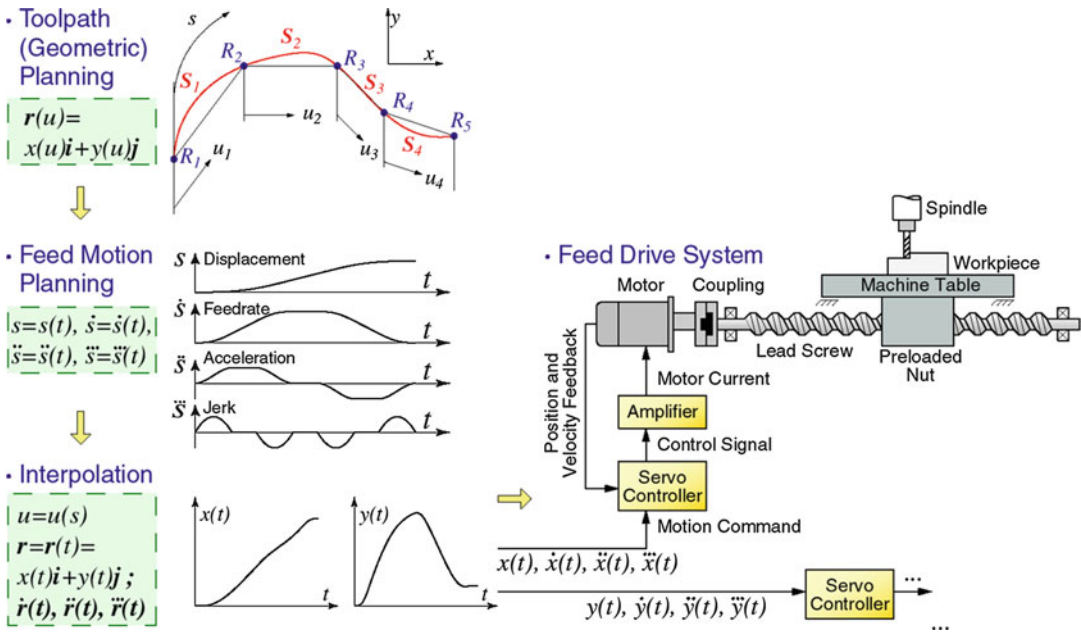
Introduction

Machining is used extensively in the manufacturing industry as a shaping process, where high product accuracy, quality, and strength are required. From automotive and aerospace components, to dies and molds, to biomedical implants, and even mobile device chassis, many manufactured products rely on the use of machining.

Machining is carried out on machine tools, which are multi-axis mechatronic systems designed to provide the relative motion between the tool and workpiece, in order to facilitate the desired cutting operation. Figure 1 illustrates a single axis of a ball screw-driven machine tool, performing a milling operation. Here, the cutting process is influenced by the motion of the servo drive. The faster the part is fed in towards the rotating cutter, the larger the cutting forces become, following a typically proportional relationship that holds for a large class of milling operations (Altintas 2012). The generated cutting forces, in turn, are absorbed by the machine tool and feed drive structure. They cause mechanical deformation and may also excite the vibration modes, if their harmonic content is near the structural natural frequencies. This may, depending on the cutting speed and tool and workpiece engagement conditions, lead to forced vibrations or chatter (Altintas 2012).

The disturbance effect of cutting forces is also felt by the servo control loop, consisting of mechanical, electrical, and digital components. This disturbance may result in the degradation of tool positioning accuracy, thereby leading to part errors. Another input that influences the quality achieved in a machining operation is the commanded trajectory. Discontinuous or poorly designed motion commands, with acceleration discontinuity, lead typically to jerky motion, vibrations, and poor surface finish. Beyond motion controller design and trajectory planning, emerging trends in machining process control include regulating, by feedback, various outcomes of the machining process, such as peak resultant cutting force, spindle power consumption, and amplitude of vibrations caused by the machining process. In addition to using actuators and instrumentation already available on a machine tool, such as feed and spindle drives and current sensors, additional devices, such as dynamometers, accelerometers, as well as inertial or piezoelectric actuators, may need to be used in order to achieve the required level of feedback and control injection capability.

Servo Drive Control

Stringent requirements for part quality, typically specified in microns, coupled with disturbance


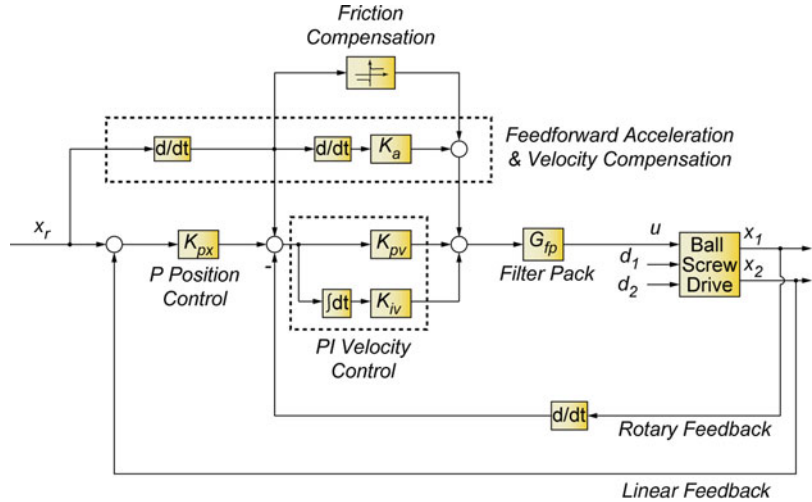
Control of Machining Processes, Fig. 1 Single axis of a ball screw-driven machine tool performing milling

force inputs coming from the machining process, which can be in the order of tens to thousands of Newtons, require that the disturbance rejection of feed drives, which act as dynamic (i.e., frequency dependent) "stiffness" elements, be kept as strong as possible. In traditional machine design, this is achieved by optimizing the mechanical structure for maximum rigidity. Afterwards, the motion control loop is tuned to yield the highest possible bandwidth (i.e., responsive frequency range), without interfering with the vibratory modes of the machine tool in a way that can cause instability. The P-PI position velocity cascade control structure, shown in Fig. 2, is the most widely used technique in machine tool drives. Its tuning guidelines have been well established in the literature (Ellis 2004). To augment the command following accuracy, velocity and acceleration feedforward, and friction compensation terms are added. Increasing the closed-loop bandwidth yields better disturbance rejection and more accurate tracking of the commanded trajectory (Pritschow 1996), which is especially important in high-speed machining applications where elevated cutting speeds necessitate faster feed motion.

It can be seen in Fig. 3 that increased axis tracking errors (e_x and e_y) may result in increased contour error (ε). A practical solution to mitigate this problem, in machine tool engineering, is to also match the dynamics of different motion axes, so that the tracking errors always assume an instantaneous proportion that brings the actual tool position as close as possible to the desired toolpath (Koren 1983). Sometimes, the control action can be designed to directly reduce the contour error as well, which leads to the structure known as "cross-coupling control" (Koren 1980).

Trajectory Planning

Smooth trajectory planning with at least acceleration level continuity is required in machine tool control, in order to avoid inducing unwanted vibration or excessive tracking error during the machining process. For this purpose, computer numerical control (CNC) systems are equipped with various spline toolpath interpolation functions, such as B-splines, and NURBS. The feedrate (i.e., progression speed along the toolpath) is planned in the "look-ahead" function of the

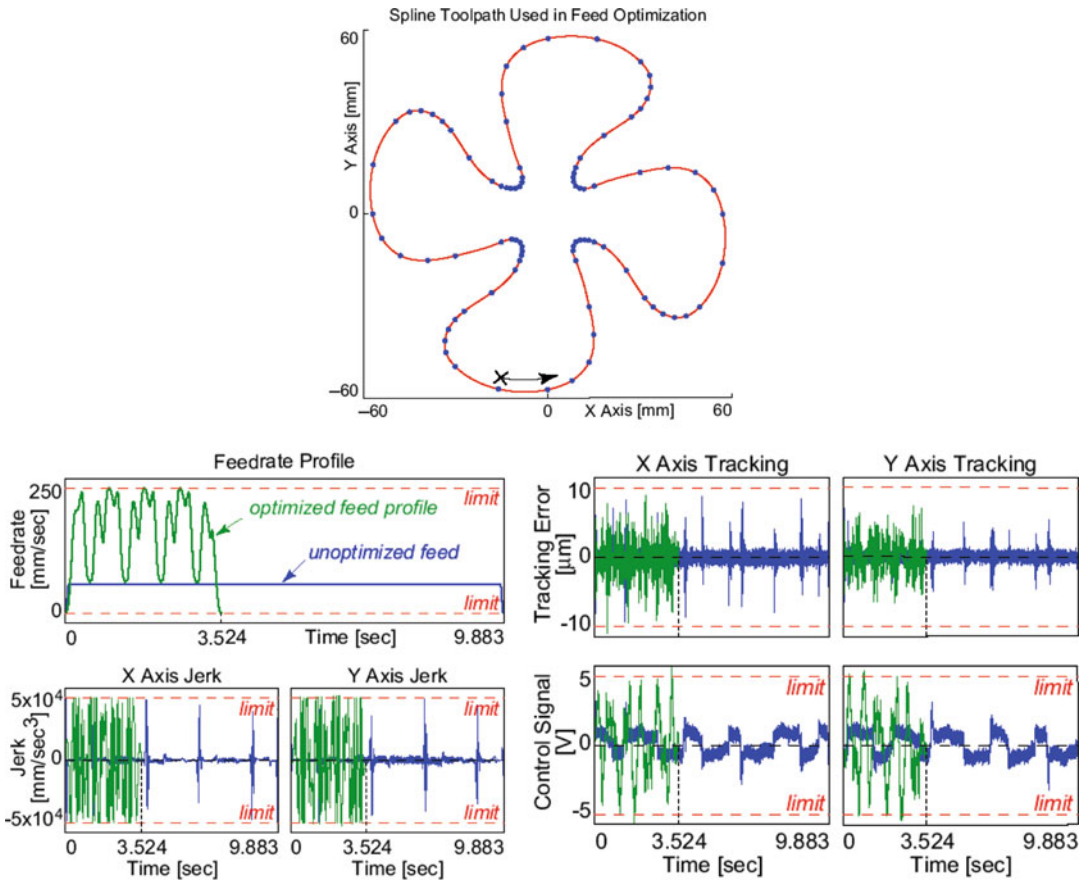
Control of Machining Processes, Fig. 2 P-PI position velocity cascade control used in machine tool drives


Control of Machining Processes, Fig. 3 Formation of contour error (ε), as a result of servo errors (e_x and e_y) in the individual axes

CNC so that the total machining cycle time is reduced as much as possible. This has to be done without violating the position-dependent feedrate limits already programmed into the numerical control (NC) code, which are specified by considering various constraints coming from the machining process.

In feedrate optimization, axis level trajectories have to stay within the velocity and torque limits of the drives, in order to avoid damaging the machine tool or causing actuator saturation. Moreover, as an indirect way of containing tracking errors, the practice of limiting axis level jerk (i.e., rate of change of acceleration) is applied (Gordon and Erkorkmaz 2013). This results in

reduced machining cycle time, while avoiding excessive vibration or positioning error due to "jerky" motion.

An example of trajectory planning using quintic (5th degree) polynomials for toolpath parameterization is shown in Fig. 4. Here, comparison is provided between unoptimized and optimized feedrate profiles subject to the same axis velocity, torque (i.e., control signal), and jerk limits. As can be seen, significant machining time reduction can be achieved through trajectory optimization, while retaining the dynamic tool position accuracy. While Fig. 4 shows the result of an elaborate nonlinear optimization approach (Altintas and Erkorkmaz 2003), practical look-ahead


Control of Machining Processes, Fig. 4 Example of quintic spline trajectory planning without and with feedrate optimization

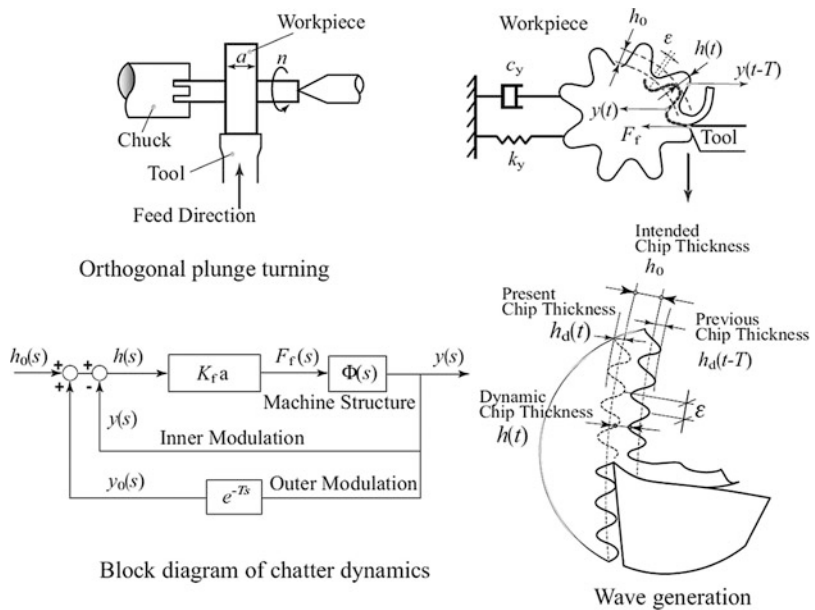
algorithms have also been proposed which lead to more conservative cycle times but are much better suited for real-time implementation inside a CNC (Weck et al. 1999).

Adaptive Control of Machining

There are established mathematical methods for predicting cutting forces, torque, power, and even surface finish for a variety of machining operations like turning, boring, drilling, and milling (Altintas 2012). However, when machining complex components, such as gas turbine impellers, or dies and molds, the tool and workpiece engagement and workpiece geometry undergo continuous change. Hence, it may be difficult to apply such prediction models efficiently, unless

they are fully integrated inside a computer-aided process planning environment, as reported for 3-axis machining by Altintas and Merdol (2007).

An alternative approach, which allows the machining process to take place within safe and efficient operating bounds, is to use feedback from the machine tool during the cutting process. This measurement can be of the cutting forces using a dynamometer or the spindle power consumption. This measurement is then used inside a feedback control loop to override the commanded feedrate value, which has direct impact on the cutting forces and power consumption. This scheme can be used to ensure that the cutting forces do not exceed a certain limit for process safety or to increase the feed when the machining capacity is underutilized, thus boosting productivity. Since the geometry and tool engagement are generally
Control of Machining Processes, Fig. 5 Example of 5-axis impeller machining with adaptive force control (Source: Budak and Kops (2000), courtesy of Elsevier)

Control of Machining Processes, Fig. 6 Schematic of the chatter vibration mechanism for one degree of freedom (From: Altintas (2012), courtesy of Cambridge University Press)


continuously varying, the coefficients of a model that relates the cutting force (or power) to the feed command are also time-varying. Furthermore, in CNC controllers, depending on the trajectory generation architecture, the execution latency of a feed override command may not always be deterministic. Due to these sources of variability, rather than using classical fixed gain feedback, machining control research has evolved around adaptive control techniques (Masory and Koren 1980; Spence and Altintas 1991), where changes in the cutting process dynamics are continuously tracked and the control law, which computes the proceeding feedrate override, is updated

accordingly. This approach has produced significant cycle time reduction in 5-axis machining of gas turbine impellers, as reported in Budak and Kops (2000) and shown in Fig. 5.

Control of Chatter Vibrations

Chatter vibrations are caused by the interaction of the chip generation mechanism with the structural dynamics of the machine, tool, and workpiece assembly (see Fig. 6). The relative vibration between the tool and workpiece generates a wavy surface finish. In the consecutive tool

pass, a new wave pattern, caused by the current instantaneous vibration, is generated on top of the earlier one. If the formed chip, which has an undulated geometry, displays a steady average thickness, then the resulting cutting forces and vibrations also remain bounded. This leads to a stable steady-state cutting regime, known as "forced vibration." On the other hand, if the chip thickness keeps increasing at every tool pass, resulting in increased cutting forces and vibrations, then chatter vibration is encountered. Chatter can be extremely detrimental to the machined part quality, tool life, and the machine tool.

Chatter has been reported in literature to be caused by two main phenomena: self-excitation through regeneration and mode coupling. For further information on chatter theory, the reader is referred to Altintas (2012) as an excellent starting point.

Various mitigation measures have been investigated and proposed in order to avoid and control chatter. One widespread approach is to select chatter-free cutting conditions through detailed modal testing and stability analyses. Recently, to achieve higher material removal rates, the application of active damping has started to receive interest. This has been realized through specially designed tools and actuators (Munoa et al. 2013; Pratt and Nayfeh 2001) and demonstrated productivity improvement in boring and milling operations. As another method for chatter suppression, modulation of the cutting (i.e., spindle) speed has been successfully applied as a means of interrupting the regeneration mechanism (Soliman and Ismail 1997; Zatarain et al. 2008).

Summary and Future Directions

This article has presented an overview of various concepts and emerging technologies in the area of machining process control. The new generation of machine tools, designed to meet the ever-growing productivity and efficiency demands, will likely utilize advanced forms of these ideas and technologies in an integrated manner. As more computational power and better sensors

become available at lower cost, one can expect to see new features, such as more elaborate trajectory planning algorithms, active vibration damping techniques, and real-time process and machine simulation and control capability, beginning to appear in CNC units. No doubt that the dynamic analysis and controller design for such complicated systems will require higher levels of rigor, so that these new technologies can be utilized reliably and at their full potential.

Control of Networks of Underwater Vehicles

Naomi Ehrich Leonard
Department of Mechanical and Aerospace
Engineering, Princeton University, Princeton,
NJ, USA

Abstract

Control of networks of underwater vehicles is critical to underwater exploration, mapping, search, and surveillance in the multiscale, spatiotemporal dynamics of oceans, lakes, and rivers. Control methodologies have been derived for tasks including feature tracking and adaptive sampling and have been successfully demonstrated in the field despite the severe challenges of underwater operations.

Keywords

Adaptive sampling; Feature tracking; Gliders; Mobile sensor arrays; Underwater exploration

Introduction

The development of theory and methodology for control of networks of underwater vehicles is motivated by a multitude of underwater applications and by the unique challenges associated with operating in the oceans, lakes, and rivers. Tasks include underwater exploration, mapping, search, and surveillance, associated with problems that include pollution monitoring, human safety, resource seeking, ocean science, and marine archeology. Vehicle networks collect data on underwater physics, biology, chemistry, and geology for improving the understanding and predictive modeling of natural dynamics and human-influenced changes in marine environments. Because the underwater environment is opaque, inhospitable, uncertain, and dynamic, control is critical to the performance of vehicle networks.

Underwater vehicles typically carry sensors to measure external environmental signals and fields, and thus a vehicle network can be regarded as a mobile sensor array. The underlying principle of control of networks of underwater vehicles leverages their mobility and uses an interacting dynamic among the vehicles to yield a high-performing collective behavior. If the vehicles can communicate their state or measure the relative state of others, then they can cooperate and coordinate their motion.

One of the major drivers of control of underwater mobile sensor networks is the multiscale, spatiotemporal dynamics of the environmental fields and signals. In Curtin et al. (1993), the concept of the autonomous oceanographic sampling network (AOSN), featuring a network of underwater vehicles, was introduced for dynamic measurement of the ocean environment and resolution of spatial and temporal gradients in the sampled fields. For example, to understand the coupled biological and physical dynamics of the ocean, data are required both on the small-scale dynamics of phytoplankton, which are major actors in the marine ecosystem and the global climate, and on the large-scale dynamics of the flow field, temperature, and salinity.

Accordingly, control laws are needed to coordinate the motion of networks of underwater vehicles to match the many relevant spatial and temporal scales. And for a network of underwater vehicles to perform complex missions reliably and efficiently, the control must address the many

uncertainties and real-world constraints including the influence of currents on the motion of the vehicles and the limitations on underwater communication.

Vehicles

Control of networks of underwater vehicles is made possible with the availability of small (e.g., 1.5–2 m long), relatively inexpensive autonomous underwater vehicles (AUVs). Propelled AUVs such as the REMUS provide maneuverability and speed. These kinds of AUVs respond quickly and agilely to the needs of the network, and because of their speed, they can often power through strong ocean flows. However, propelled AUVs are limited by their batteries; for extended missions, they need docking stations or other means to recharge their batteries.

Buoyancy-driven autonomous underwater gliders, including the Slocum, the Spray, and the Seaglider, are a class of endurance AUVs designed explicitly for collecting data over large three-dimensional volumes continuously over periods of weeks or even months (Rudnick et al. 2004). They move slowly and steadily, and, as a result, they are particularly well suited to network missions of long duration.

Gliders propel themselves by alternately increasing and decreasing their buoyancy using either a hydraulic or a mechanical buoyancy engine. Lift generated by flow over fixed wings converts the vertical ascent/descent induced by the change in buoyancy into forward motion, resulting in a sawtooth-like trajectory in the vertical plane. Gliders can actively redistribute internal mass to control attitude, for example, they pitch by sliding their battery pack forward and aft. For heading control, they shift mass to roll, bank, and turn or deflect a rudder. Some gliders are designed for deep water, e.g., to 1,500 m, while others for shallower water, e.g., to 200 m.

Gliders are typically operated at their maximum speed and thus they move at approximately constant speed relative to the flow. Because this is relatively slow, on the order of 0.3–0.5 m/s in the horizontal direction and 0.2 m/s in the vertical,

ocean currents can sometimes reach or even exceed the speed of the gliders. Unlike a propelled AUV, which typically has sufficient thrust to maintain course despite currents, a glider trying to move in the direction of a strong current will make no forward progress. This makes coordinated control of gliders challenging; for instance, two sensors that should stay sufficiently far apart may be pushed toward each other leading to less than ideal sampling conditions.

Communication and Sensing

Underwater communication is one of the biggest challenges to the control of networks of underwater vehicles and one that distinguishes it from control of vehicles on land or in the air. Radio-frequency communication is not typically available underwater, and acoustic data telemetry has limitations including sensitivity to ambient noise, unpredictable propagation, limited bandwidth, and latency.

When acoustic communication is too limiting, vehicles can surface periodically and communicate via satellite. This method may be bandwidth limited and will require time and energy. However, in the case of profiling propelled AUVs or underwater gliders, they already move in the vertical plane in a sawtooth pattern and thus regularly come closer to the surface. When on the surface, vehicles can also get a GPS fix whereas there is no access to GPS underwater. The GPS fix is used for correcting onboard dead reckoning of the vehicle's absolute position and for updating onboard estimation of the underwater currents, both helpful for control.

Vehicles are typically equipped with conductivity-temperature-density (CTD) sensors to measure temperature, salinity, and density. From this pressure can be computed and thus depth and vertical speed. Attitude sensors provide measurements of pitch, roll, and heading. Position and velocity in the plane is estimated using dead reckoning. Many sensors for measuring the environment have been developed for use on underwater vehicles; these include chlorophyll fluorometers to estimate phytoplankton abundance, acoustic Doppler

profilers (ADPs) to measure variations in water velocity, and sensors to measure pH, dissolved oxygen, and carbon dioxide.

Control

Described here are a selection of control methodologies designed to serve a variety of underwater applications and to address many of the challenges described above for both propelled AUVs and underwater gliders. Some of these methodologies have been successfully field tested in the ocean.

Formations for Tracking Gradients, Boundaries, and Level Sets in Sampled Fields

While a small underwater vehicle can take only single-point measurements of a field, a network of N vehicles employing cooperative control laws can move as a formation and estimate or track a gradient in the field. This can be done in a straightforward way in 2D with three vehicles and can be extended to 3D with additional vehicles. Consider $N = 3$ vehicles moving together in an equilateral triangular formation and sampling a 2D field $T : \mathbb{R}^2 \to \mathbb{R}$. The formation serves as a sensor array and the triangle side length defines the resolution of the array.

Let the position of the ith vehicle be $\mathbf{x}_i \in \mathbb{R}^2$. Consider double integrator dynamics $\ddot{\mathbf{x}}_i = \mathbf{u}_i$, where $\mathbf{u}_i \in \mathbb{R}^2$ is the control force on the ith vehicle. Suppose that each vehicle can measure the relative position of each of its neighbors, $\mathbf{x}_{ij} = \mathbf{x}_i - \mathbf{x}_j$. Decentralized control that derives from an artificial potential is a popular method for each of the three vehicles to stay in the triangular formation of prescribed resolution d_0. Consider the nonlinear interaction potential $V_I : \mathbb{R}^2 \to \mathbb{R}$ defined as

$$V_I(\mathbf{x}_{ij}) = k_s \left(\ln \|\mathbf{x}_{ij}\| + \frac{d_0}{\|\mathbf{x}_{ij}\|^2} \right)$$

where $k_s > 0$ is a scalar gain. The control law for the ith vehicle derives as the gradient of this potential with respect to $\mathbf{x}_i$ as follows:

$$\ddot{\mathbf{x}}_i = \mathbf{u}_i = - \sum_{j=1, j \neq i}^{N} \nabla V_I(\mathbf{x}_{ij}) - k_d \dot{\mathbf{x}}_i$$

where a damping term is added with scalar gain $k_d > 0$. Stability of the triangle of resolution d_0 is proved with the Lyapunov function

$$V = \frac{1}{2} \sum_{i=1}^{N} \|\dot{\mathbf{x}}_i\|^2 + \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} V_I(\mathbf{x}_{ij}).$$

Now let each vehicle use the sequence of single-point measurements it takes along its path to compute the projection of the spatial gradient onto its normalized velocity, $\mathbf{e}_{\dot{\mathbf{x}}} = \dot{\mathbf{x}}_i / \|\dot{\mathbf{x}}_i\|$, i.e., $\nabla T_P(\mathbf{x}, \dot{\mathbf{x}}_i) = (\nabla T(\mathbf{x}) \cdot \mathbf{e}_{\dot{\mathbf{x}}}) \mathbf{e}_{\dot{\mathbf{x}}}$. Following Bachmayer and Leonard (2002), let

$$\ddot{\mathbf{x}}_i = \mathbf{u}_i = \kappa \nabla T_P(\mathbf{x}, \dot{\mathbf{x}}_i) - \sum_{j=1, j \neq i}^{N} \nabla V_I(\mathbf{x}_{ij}) - k_d \dot{\mathbf{x}}_i,$$

where κ is a scalar gain. For $\kappa > 0$, each vehicle will accelerate along its path when it measures an increasing T and decelerates for a decreasing T. Each vehicle will also turn to keep up with the others so that the formation will climb the spatial gradient of T to find a local maximum.

Alternative control strategies have been developed that add versatility in feature tracking. The virtual body and artificial potential (VBAP) multivehicle control methodology (Ögren et al. 2004) was demonstrated with a network of Slocum autonomous underwater gliders in the AOSN II field experiment in Monterey Bay, California, in August 2003 (Fiorelli et al. 2006). VBAP is well suited to the operational scenario described above in which vehicles surface asynchronously to establish communication with a base.

VBAP is a control methodology for coordinating the translation, rotation, and dilation of a group of vehicles. A virtual body is defined by a set of reference points that move according to dynamics that are computed centrally and made available to the vehicles in the group. Artificial potentials are used to couple the dynamics of vehicles and a virtual body so that control laws can be derived that stabilize desired formations of vehicles and a virtual body. When sampled

measurements of a scalar field can be communicated, the local gradients can be estimated. Gradient climbing algorithms prescribe virtual body direction, so that, for example, the vehicle network can be directed to head for the coldest water or the highest concentration of phytoplankton. Further, the formation can be dilated so that the resolution can be adapted to minimize error in estimates. Control of the speed of the virtual body ensures stability and convergence of the vehicle formation.

These ideas have been extended further to design provable control laws for cooperative level set tracking, whereby small vehicle groups cooperate to generate contour plots of noisy, unknown fields, adjusting their formation shape to provide optimal filtering of their noisy measurements (Zhang and Leonard 2010).

Motion Patterns for Adaptive Sampling

A central objective in many underwater applications is to design provable and reliable mobile sensor networks for collecting the richest data set in an uncertain environment given limited resources. Consider the sampling of a single time- and space-varying scalar field, like temperature T, using a network of vehicles, where the control problem is to coordinate the motion of the network to maximize information on this field over a given area or volume.

The definition of the information metric will depend on the application. If the data are to be assimilated into a high-resolution dynamical ocean model, then the metric would be defined by uncertainty as computed by the model. A general-purpose metric, based on objective analysis (linear statistical estimation from given field statistics), specifies the statistical uncertainty of the field model as a function of where and when the data were taken (Bennett 2002). The posteriori error $A(\mathbf{r}, t)$ is the variance of T about its estimate at location $\mathbf{r}$ and time t. Entropic information over a spatial domain of area $\mathcal{A}$ is

$$\mathcal{I}(t) = -\log\left(\frac{1}{\sigma_0 \mathcal{A}} \int d\mathbf{r}\, A(\mathbf{r}, t)\right),$$

where σ_0 is a scaling factor (Grocholsky 2002).

Computing coordinated trajectories to maximize $\mathcal{I}(t)$ can in principle be addressed using optimal coverage control methods. However, this coverage problem is especially challenging since the uncertainty field is spatially nonuniform and it changes with time and with the motion of the sampling vehicles. Furthermore, the optimal trajectories may become quite complex so that controlling vehicles to them in the presence of dynamic disturbances and uncertainty may lead to suboptimal performance.

An alternative approach decouples the design of motion patterns to optimize the entropic information metric from the decentralized control laws that stabilize the network onto the motion patterns (see Leonard et al. 2007). This approach was demonstrated with a network of 6 Slocum autonomous underwater gliders in a 24-day-long field experiment in Monterey Bay, California, in August 2006 (see Leonard et al. 2010). The coordinating feedback laws for the individual vehicles derive systematically from a control methodology that provides provable stabilization of a parameterized family of collective motion patterns (Sepulchre et al. 2008). These patterns consist of vehicles moving on a finite set of closed curves with spacing between vehicles defined by a small number of "synchrony" parameters. The feedback laws that stabilize a given motion pattern use the same synchrony parameters that distinguish the desired pattern.

Each vehicle moves in response to the relative position and direction of its neighbors so that it keeps moving, it maintains the desired spacing, and it stays close to its assigned curve. It has been observed in the ocean, for vehicles carrying out this coordinated control law, that "when a vehicle on a curve is slowed down by a strong opposing flow field, it will cut inside a curve to make up distance and its neighbor on the same curve will cut outside the curve so that it does not overtake the slower vehicle and compromise the desired spacing" (Leonard et al. 2010). The approach is robust to vehicle failure since there are no leaders in the network, and it is scalable since the control law for each vehicle can be defined in terms of the state of a few other vehicles, independent of the total number of vehicles.

The control methodology prescribes steering laws for vehicles operated at a constant speed. Assume that the ith vehicle moves at unit speed in the plane in the direction $\theta_i(t)$ at time t. Then, the velocity of the ith vehicle is $\dot{\mathbf{x}}_i = (\cos\theta_i, \sin\theta_i)$. The steering control u_i is the component of the force in the direction normal to velocity, such that $\dot{\theta}_i = u_i$ for $i = 1, \ldots, N$. Define

$$U(\theta_1, \ldots, \theta_N) = \frac{N}{2}\|\mathbf{p}_\theta\|^2, \quad \mathbf{p}_\theta = \frac{1}{N}\sum_{j=1}^{N}\dot{\mathbf{x}}_j.$$

U is a potential function that is maximal at 1 when all vehicle directions are synchronized and minimal at 0 when all vehicle directions are perfectly anti-synchronized. Let $\tilde{\mathbf{x}}_i = (\tilde{x}_i, \tilde{y}_i) = (1/N)\sum_{j=1}^{N}\mathbf{x}_{ij}$ and let $\tilde{\mathbf{x}}_i^\perp = (-\tilde{y}_i, \tilde{x}_i)$. Define

$$S(\mathbf{x}_1, \ldots, \mathbf{x}_N, \theta_1, \ldots, \theta_N) = \frac{1}{2}\sum_{i=1}^{N}\|\dot{\mathbf{x}}_i - \omega_0\tilde{\mathbf{x}}_i^\perp\|^2,$$

where $\omega_0 \neq 0$. S is a potential function that is minimal at 0 for circular motion of the vehicles around their center of mass with radius $\rho_0 = |\omega_0|^{-1}$.

Define the steering control as

$$\dot{\theta}_i = \omega_0(1 + K_c\langle\tilde{\mathbf{x}}_i, \dot{\mathbf{x}}_i\rangle) - K_\theta\sum_{j=1}^{N}\sin(\theta_j - \theta_i),$$

where $K_c > 0$ and K_θ are scalar gains. Then, circular motion of the network is a steady solution, with the phase-locked heading arrangement a minimum of $K_\theta U$, i.e., synchronized or perfectly anti-synchronized depending on the sign of K_θ. Stability can be proved with the Lyapunov function $V_{c\theta} = K_c S + K_\theta U$. This steering control law depends only on relative position and relative heading measurements of the other vehicles.

The general form of the methodology extends the above control law to network interconnections defined by possibly time-varying graphs with limited sensing or communication links, and it provides systematic control laws to stabilize symmetric patterns of heading distributions about noncircular closed curves. It also allows

for multiple graphs to handle multiple scales. For example, in the 2006 field experiment, the default motion pattern was one in which six gliders moved in coordinated pairs around three closed curves; one graph defined the smaller-scale coordination of each pair of gliders about its curve, while a second graph defined the larger-scale coordination of gliders across the three curves.

Implementation

Implementation of control of networks of underwater vehicles requires coping with the remote, hostile underwater environment. The control methodology for motion patterns and adaptive sampling, described above, was implemented in the field using a customized software infrastructure called the Glider Coordinated Control System (GCCS) (Paley et al. 2008). The GCCS combines a simple model for control planning with a detailed model of glider dynamics to accommodate the constant speed of gliders, relatively large ocean currents, waypoint tracking routines, communication only when gliders surface (asynchronously), other latencies, and more. Other approaches consider control design in the presence of a flow field, formal methods to integrate high-resolution models of the flow field, and design tailored to propelled AUVs.

Summary and Future Directions

The multiscale, spatiotemporal dynamics of the underwater environment drive the need for well-coordinated control of networks of underwater vehicles that can manage the significant operational challenges of the opaque, uncertain, inhospitable, and dynamic oceans, lakes, and rivers. Control theory and algorithms have been developed to enable networks of vehicles to successfully operate as adaptable sensor arrays in missions that include feature tracking and adaptive sampling. Future work will improve control in the presence of strong and unpredictable flow

fields and will leverage the latest in battery and underwater communication technologies. Hybrid vehicles and heterogeneous networks of vehicles will also promote advances in control. Future work will draw inspiration from the rapidly growing literature in decentralized cooperative control strategies and complex dynamic networks. Dynamics of decision-making teams of robotic vehicles and humans is yet another important direction of research that will impact the success of control of networks of underwater vehicles.

Control of Nonlinear Systems with Delays

Nikolaos Bekiaris-Liberis and Miroslav Krstic
Department of Mechanical and Aerospace Engineering, University of California, San Diego, La Jolla, CA, USA

Abstract

The reader is introduced to the predictor feedback method for the control of general nonlinear systems with input delays of arbitrary length. The delays need not necessarily be constant but can be time-varying or state-dependent. The predictor feedback methodology employs a model-based construction of the (unmeasurable) future state of

the system. The analysis methodology is based on the concept of infinite-dimensional backstepping transformation – a transformation that converts the overall feedback system to a new, cascade "target system" whose stability can be studied with the construction of a Lyapunov function.

Keywords

Distributed parameter systems; Delay systems; Backstepping; Lyapunov function

Nonlinear Systems with Input Delay

Nonlinear systems of the form

$$\dot{X}(t) = f\left(X(t), U\left(t - D\left(t, X(t)\right)\right)\right), \quad (1)$$

where $t \in \mathbb{R}_+$ is time, $f : \mathbb{R}^n \times \mathbb{R} \to \mathbb{R}^n$ is a vector field, $X \in \mathbb{R}^n$ is the state, $D : \mathbb{R}_+ \times \mathbb{R}^n \to \mathbb{R}_+$ is a nonnegative function of the state of the system, and $U \in \mathbb{R}$ is the scalar input, are ubiquitous in applications. The starting point for designing a control law for (1), as well as for analyzing the dynamics of (1) is to consider the delay-free counterpart of (1), i.e., when $D = 0$, for which a plethora of results exists dealing with its stabilization and Lyapunov-based analysis (Krstic et al 1995).

Systems of the form (1) constitute more realistic models for physical systems than delay-free systems. The reason is that often in engineering applications the control that is applied to the system does not immediately affect the system. This dead time until the controller can affect the system might be due to, among other things, the long distance of the controller from the system, such as, for example, in networked control systems, or due to finite-speed transport or flow phenomena, such as, for example, in additive manufacturing and cooling systems, or due to various after-effects, such as, for example, in population dynamics.

The first step toward control design and analysis for system (1) is to consider the special case in which $D = $ const. The next step is to consider the special case of system (1), in which $D = D(t)$, i.e., the delay is an a priori given function of time. Systems with time-varying delays model numerous real-world systems, such as, networked control systems, traffic systems, or irrigation channels. Assuming that the input delay is an a priori defined function of time is a plausible assumption for some applications. Yet, the time-variation of the delay might be the result of the variation of a physical quantity that has its own dynamics, such as, for example, in milling processes (due to speed variations), 3D printers (due to distance variations), cooling systems (due to flow rate variations), and population dynamics (due to population's size variations). Processes in this category can be modeled by systems with a delay that is a function of the state of the system, i.e., by (1) with $D = D(X)$.

In this article control designs are presented for the stabilization of nonlinear systems with input delays, with delays that are constant (Krstic 2009), time-varying (Bekiaris-Liberis and Krstic 2012) or state-dependent (Bekiaris-Liberis and Krstic 2013b), employing predictor feedback, i.e., employing a feedback law that uses the future rather than the current state of the system. Since one employs in the feedback law the future values of the state, the predictor feedback completely cancels (compensates) the input delay, i.e., after the control signal reaches the system, the state evolves as if there were no delay at all. Since the future values of the state are not a priori known, the main control challenge is the implementation of the predictor feedback law. Having determined the predictor, the control law is then obtained by replacing the current state in a nominal state-feedback law (which stabilizes the delay-free system) by the predictor.

A methodology is presented in the article for the stability analysis of the closed-loop system under predictor feedback by constructing Lyapunov functionals. The Lyapunov functionals are constructed for a transformed (rather than

the original) system. The transformed system is, in turn, constructed by transforming the original actuator state $U(\theta)$, $\theta \in [t - D, t]$ to a transformed actuator state with the aid of an infinite-dimensional backstepping transformation. The overall transformed system is easier to analyze than the original system because it is a cascade, rather than a feedback system, consisting of a delay line with zero input, whose effect fades away in finite time, namely, after D time units, cascaded with an asymptotically stable system.

Predictor Feedback

The predictor feedback designs are based on a feedback law $U(t) = \kappa(X(t))$ that renders the closed-loop system $\dot{X} = f(X, \kappa(X))$ globally asymptotically stable. For stabilizing system (1), the following control law is employed instead

$$U(t) = \kappa(P(t)), \tag{2}$$

where

$$P(\theta) = X(t) + \int_{t-D(t,X(t))}^{\theta} \frac{f(P(s), U(s))}{1 - D_t(\sigma(s), P(s)) - \nabla D(\sigma(s), P(s)) f(P(s), U(s))} ds \tag{3}$$

$$\sigma(\theta) = t + \int_{t-D(t,X(t))}^{\theta} \frac{1}{1 - D_t(\sigma(s), P(s)) - \nabla D(\sigma(s), P(s)) f(P(s), U(s))} ds, \tag{4}$$

for all $t - D(t, X(t)) \leq \theta \leq t$. The signal P is the predictor of X at the appropriate prediction time σ, i.e., $P(t) = X(\sigma(t))$. This fact is explained in more detail in the next paragraphs of this section. The predictor employs the future values of the state X which are not a priori available. Therefore, for actually implementing the feedback law (2) one has to employ (3). Relation (3) is a formula for the future values of the state that depends on the available measured quantities, i.e., the current state $X(t)$ and the history of the actuator state $U(\theta)$, $\theta \in [t - D(t, X(t)), t]$. To make clear the definitions of the predictor P and the prediction time σ, as well as their implementation through formulas (3) and (4), the constant delay case is discussed first.

The idea of predictor feedback is to employ in the control law the future values of the state at the appropriate future time, such that the effect of the input delay is completely canceled (compensated). Define the quantity $\phi(t) = t - D$, which from now on is referred to as the delayed time. This is the time instant at which the control signal that currently affects the system

was actually applied. To cancel the effect of this delay, the control law (2) is designed such that $U(\phi(t)) = U(t - D) = \kappa(X(t))$, i.e., such that $U(t) = \kappa(X(\phi^{-1}(t))) = \kappa(X(t + D))$. Define the prediction time σ through the relation $\phi^{-1}(t) = \sigma(t) = t + D$. This is the time instant at which an input signal that is currently applied actually affects the system. In the case of a constant delay, the prediction time is simply D time-units in the future. Next an implementable formula for $X(\sigma(t)) = X(t + D)$ is derived. Performing a change of variables $t = \theta + D$, for all $t - D \leq \theta \leq t$ in $\dot{X}(t) = f(X(t), U(t - D))$ and integrating in θ starting at $\theta = t - D$, one can conclude that P defined by (3) with $D_t = \nabla D f = 0$ and $D = $ const is the D time-units ahead predictor of X, i.e., $P(t) = X(\sigma(t)) = X(t + D)$.

To better understand definition (3) the case of a linear system with a constant input delay D, i.e., a system of the form $\dot{X}(t) = AX(t) + BU(t - D)$, is considered next (see also ► Control of Linear Systems with Delays and Hale and Verduyn Lunel (1993)). In this case, the predictor $P(t)$ is given explicitly

using the variation of constants formula, with the initial condition $P(t - D) = X(t)$, as $P(t) = e^{AD}X(t) + \int_{t-D}^{t} e^{A(t-\theta)}BU(\theta)d\theta$. For systems that are nonlinear, $P(t)$ cannot be written explicitly, for the same reason that a nonlinear ODE cannot be solved explicitly. So $P(t)$ is represented implicitly using the nonlinear integral equation (3). The computation of $P(t)$ from (3) is straightforward with a discretized implementation in which $P(t)$ is assigned values based on the right-hand side of (3), which involves earlier values of P and the values of the input U.

The case $D = D(t)$ is considered next. As in the case of constant delays the main goal is to implement the predictor P. One needs first to define the appropriate time interval over which the predictor of the state is needed, which, in the constant delay case is simply D time-units in the future. The control law has to satisfy $U(\phi(t)) = \kappa(X(t))$, or, $U(t) = \kappa(X(\sigma(t)))$. Hence, one needs to find an implementable formula for $P(t) = X(\sigma(t))$. In the constant delay case the prediction horizon over which one needs to compute the predictor can be determined based on the knowledge of the delay time since the prediction horizon and the delay time are both equal to D. This is not anymore true in the time-varying case in which the delayed time is defined as $\phi(t) = t - D(t)$, whereas the prediction time as $\phi^{-1}(t) = \sigma(t) = t + D(\sigma(t))$. Employing a change of variables in $\dot{X}(t) = f(X(t), U(t - D(t)))$ as $t = \sigma(\theta)$, for all $\phi(t) \leq \theta \leq t$ and integrating in θ starting at $\theta = \phi(t)$ one obtains the formula for P given by (3) with $D_t = D'(\sigma(t))$, $\nabla Df = 0$ and $D = D(t)$.

Next the case $D = D(X(t))$ is considered. First one has to determine the predictor, i.e., the signal P such that $P(t) = X(\sigma(t))$, where $\sigma(t) = \phi^{-1}(t)$ and $\phi(t) = t - D(X(t))$. In the case of state-dependent delay, the prediction time $\sigma(t)$ depends on the predictor itself, i.e., the time when the current control reaches the system depends on the value of the state at that time, namely, the following implicit relationship holds $P(t) = X(t + D(P(t)))$

(and $X(t) = P(t - D(X(t)))$). This implicit relation can be solved by proceeding as in the time-varying case, i.e., by performing the change of variables $t = \sigma(\theta)$, for all $t - D(X(t)) \leq \theta \leq t$ in $\dot{X}(t) = f(X(t), U(t - D(X(t))))$ and integrating in θ starting at $\theta = t - D(X(t))$, to obtain the formula (3) for P with $D_t = 0$, $\nabla Df = \nabla D(P(s))f(P(s), U(s))$ and $D = D(X(t))$.

Analogously, one can derive the predictor for the case $D = D(t, X(t))$ with the difference that now the prediction time is not given explicitly in terms of P, but it is defined through an implicit relation, namely, it holds that $\sigma(t) = t + D(\sigma(t), P(t))$. Therefore, for actually computing σ one has to proceed as in the derivation of P, i.e., to differentiate relation $\sigma(\theta) = \theta + D(\sigma(\theta), P(\theta))$ and then integrate starting at the known value $\sigma(t - D(t, X(t))) = t$. It is important to note that the integral equation (4) is needed in the computation of P only when D depends on both X and t.

Backstepping Transformation and Stability Analysis

The predictor feedback designs are based on a feedback law $\kappa(X)$ that renders the closed-loop system $\dot{X} = f(X, \kappa(X))$ globally asymptotically stable. However, in the rest of the section it is assumed that the feedback law $\kappa(X)$ renders the closed-loop system $\dot{X} = f(X, \kappa(X) + v)$ input-to-state stable (ISS) with respect to v, i.e., there exists a smooth function $S : \mathbb{R}^n \to \mathbb{R}_+$ and class $\mathcal{K}_\infty$ functions $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ such that

$$\alpha_3(|X(t)|) \leq S(X(t))$$
$$\leq \alpha_4(|X(t)|) \qquad (5)$$

$$\frac{\partial S(X(t))}{\partial X} f(X(t), \kappa(X(t)))$$
$$+ v(t)) \leq -\alpha_1(|X(t)|) + \alpha_2(|v(t)|). \qquad (6)$$

Imposing this stronger assumption enables one to construct a Lyapunov functional for the

closed-loop systems (1)–(4) with the aid of the Lyapunov characterization of ISS defined in (5) and (6).

The stability analysis of the closed-loop systems (1)–(4) is explained next. Denote the infinite-dimensional backstepping transformation of the actuator state as

$$W(\theta) = U(\theta) - \kappa(P(\theta)),$$
$$\text{for all } t - D(t, X(t)) \le \theta \le t, \quad (7)$$

where $P(\theta)$ is given in terms of $U(\theta)$ from (3). Using the fact that $P(t - D(t, X(t))) = X(t)$, for all $t \ge 0$, one gets from (7) that $U(t - D(t, X(t))) = W(t - D(t, X(t))) + \kappa(X(t))$. With the fact that for all $\theta \ge 0$, $U(\theta) = \kappa(P(\theta))$ one obtains from (7) that $W(\theta) = 0$, for all $\theta \ge 0$. Yet, for all $t \le D(t, X(t))$, i.e., for all $\theta \le 0$, $W(\theta)$ might be nonzero due to the effect of the arbitrary initial condition $U(\theta)$, $\theta \in [-D(0, X(0)), 0]$. With the above observations, one can transform system (1) with the aid of transformation (7) to the following target system

$$\dot{X}(t) = f(X(t), \kappa(X(t))$$
$$+ W(t - D(t, X(t)))) \quad (8)$$
$$W(t - D(t, X(t))) = 0,$$
$$\text{for } t - D(t, X(t)) \ge 0. \quad (9)$$

Using relations (5), (6), and (8), (9) one can construct the following Lyapunov functional for showing asymptotic stability of the target system (8), (9), i.e., for the overall system consisting of the vector $X(t)$ and the transformed infinite-dimensional actuator state $W(\theta)$, $t - D(t, X(t)) \le \theta \le t$,

$$V(t) = S(X(t)) + \frac{2}{c} \int_0^{L(t)} \frac{\alpha_2(r)}{r} dr, \quad (10)$$

where $c > 0$ is arbitrary and

$$L(t) = \sup_{t - D(t, X(t)) \le \theta \le t} \left| e^{c(\sigma(\theta) - t)} W(\theta) \right|. \quad (11)$$

With the invertibility of the backstepping transformation one can then show global asymptotic stability of the closed-loop system in the original variables (X, U). In particular, there exists a class $\mathcal{KL}$ function β such that

$$|X(t)| + \sup_{t - D(t, X(t)) \le \theta \le t} |U(\theta)|$$

$$\le \beta \left(|X(0)| + \sup_{-D(0, X(0)) \le \theta \le 0} |U(\theta)|, t \right),$$

$$\text{for all } t \ge 0. \quad (12)$$

One of the main obstacles in designing globally stabilizing control laws for nonlinear systems with long input delays is the finite escape phenomenon. The input delay may be so large that the control signal cannot reach the system before its state grows unbounded. Therefore, one has to assume that the system $\dot{X} = f(X, \omega)$ is forward complete, i.e., for every initial condition and every bounded input signal the corresponding solution is defined for all $t \ge 0$.

With the forward completeness requirement, estimate (12) holds globally for constant but arbitrary large delays. For the case of time-varying delays, estimate (12) holds globally as well but under the following four conditions on the delay:

C1. $D(t) \ge 0$. This condition guarantees the causality of the system.

C2. $D(t) < \infty$. This condition guarantees that all inputs applied to the system eventually reach the system.

C3. $\dot{D}(t) < 1$. This condition guarantees that the system never feels input values that are older than the ones it has already felt, i.e., the input signal's direction never gets reversed. (This condition guarantees the existence of $\sigma = \phi^{-1}$.)

C4. $\dot{D}(t) > -\infty$ This condition guarantees that the delay cannot disappear instantaneously, but only gradually.

In the case of state-dependent delays, the delay depends on time as a result of its dependency on the state. Therefore, predictor feedback guarantees stabilization of the system when the delay satisfies the four conditions C1–C4. Yet, since

the delay is a nonnegative function of the state, conditions C2–C4 are satisfied by restricting the initial state X and the initial actuator state. Therefore estimate (12) holds locally.

Recommended Reading

The main control design tool for general systems with input delays of arbitrary length is predictor feedback. The reader is referred to Artstein (1982) for the first systematic treatment of general linear systems with constant input delays. The applicability of predictor feedback was extended in Krstic (2009) to several classes of systems, such as nonlinear systems with constant input delays and linear systems with unknown input delays. Subsequently, predictor feedback was extended to general nonlinear systems with nonconstant input and state delays (Bekiaris-Liberis and Krstic 2013a). The main stability analysis tool for systems employing predictor feedback is backstepping. Backstepping was initially introduced for adaptive control of finite-dimensional nonlinear systems (Krstic et al 1995). The continuum version of backstepping was originally developed for the boundary control of several classes of PDEs in Krstic and Smyshlyaev (2008).

Control of Quantum Systems

Ian R. Petersen
School of Engineering and Information Technology, University of New South Wales, the Australian Defence Force Academy, Canberra, Australia

Abstract

Quantum control theory is concerned with the control of systems whose dynamics are governed by the laws of quantum mechanics. Quantum control may take the form of open loop quantum control or quantum feedback control. Also, quantum feedback control may consist of measurement based feedback control, in which the controller is a classical system governed by the laws of classical physics. Alternatively, quantum feedback control may take the form of coherent feedback control in which the controller is a quantum system governed by the laws of quantum mechanics. In the area of open loop quantum control, questions of controllability along with optimal control and Lyapunov control methods are discussed. In the case of quantum feedback control, LQG and H^∞ control methods are discussed.

Introduction

Quantum control is the control of systems whose dynamics are described by the laws of quantum physics rather than classical physics. The dynamics of quantum systems must be described using quantum mechanics which allows for uniquely quantum behavior such as entanglement and coherence. There are two main approaches to quantum mechanics which are referred to as the Schrödinger picture and the Heisenberg picture. In the Schrödinger picture, quantum systems are modeled using the Schrödinger equation or a master equation which describe the evolution of the system state or density operator. In the Heisenberg picture, quantum systems are modeled using quantum stochastic differential equations which describe the evolution of system observables. These different approaches to quantum mechanics lead to different approaches to quantum control. Important areas in which quantum control problems arise include physical chemistry, atomic and molecular physics, and optics. Detailed overviews of the field o quantum control can be found in the survey papers Dong and Petersen (2010) and Brif et al. (2010) and the monographs Wiseman and Milburn (2010) and D'Alessandro (2007).

A fundamental problem in a number of approaches to quantum control is the controllability problem. Quantum controllability problems are concerned with finite dimensional quantum systems modeled using the Schrödinger picture of quantum mechanics and involves the structure of corresponding Lie groups or Lie algebras; e.g., see D'Alessandro (2007). These problems are typically concerned with closed quantum systems which are quantum systems isolated from their environment. For a controllable quantum system, an open loop control strategy can be constructed in order to manipulate the quantum state of the system in a general way. Such open loop control strategies are referred to as coherent control strategies. Time optimal control is one method of constructing these control strategies which has been applied in applications including physical chemistry and in nuclear magnetic resonance systems; e.g., see Khaneja et al. (2001).

An alternative approach to open loop quantum control is the Lyapunov approach; e.g., see Wang and Schirmer (2010). This approach extends the classical Lyapunov control approach in which a control Lyapunov function is used to construct a stabilizing state feedback control law. However in quantum control, state feedback control is not allowed since classical measurements change the quantum state of a system and the Heisenberg uncertainty principle forbids the simultaneous exact classical measurement of noncommuting quantum variables. Also, in many quantum control applications, the timescales are such that real time classical measurements are not technically feasible. Thus, in order to obtain an open loop control strategy, the deterministic closed loop system is simulated as if the state feedback control were available and this enables an open loop control strategy to be constructed. As an alternative to coherent open loop control strategies, some classical measurements may be introduced leading to incoherent control strategies; e.g., see Dong et al. (2009).

In addition to open loop quantum control approaches, a number of approaches to quantum control involve the use of feedback; e.g., see Wiseman and Milburn (2010). This quantum feedback may either involve the use of classical measurements, in which case the controller is a classical (nonquantum) system or it may involve the case where no classical measurements are used since the controller itself is a quantum system. The case in which the controller itself is a quantum system is referred to as coherent quantum feedback control; e.g., see Lloyd (2000) and James et al. (2008). Quantum feedback control may be considered using the Schrödinger picture, in which case the quantum systems under consideration are modeled using stochastic master equations. Alternatively using the Heisenberg picture, the quantum systems under consideration are modeled using quantum stochastic differential equations. Applications in which quantum feedback control can be applied include quantum optics and atomic physics. In addition, quantum control can potentially be applied to problems in quantum information (e.g., see Nielsen and Chuang 2000) such as quantum

error correction (e.g., see Kerckhoff et al. 2010) or the preparation of quantum states. Quantum information and quantum computing in turn have great potential in solving intractable computing problems such as factoring large integers using Shor's algorithm; see Shor (1994).

Schrödinger Picture Models of Quantum Systems

The state of a closed quantum system can be represented by a unit vector $|\psi\rangle$ in a complex Hilbert space $\mathcal{H}$. Such a quantum state is also referred to as a wavefunction. In the Schrödinger picture, the time evolution of the quantum state is defined by the Schrödinger equation which is in general a partial differential equation. An important class of quantum systems are finite-level systems in which the Hilbert space is finite dimensional. In this case, the Schrödinger equation is a linear ordinary differential equation of the form

$$i\hbar \frac{\partial}{\partial t}|\psi(t)\rangle = H_0 |\psi(t)\rangle$$

where H_0 is the free Hamiltonian of the system, which is a self-adjoint operator on $\mathcal{H}$; e.g., see Merzbacher (1970). Also, $\hbar$ is the reduced Planck's constant, which can be assumed to be one with a suitable choice of units. In the case of a controlled closed quantum system, this differential equation is extended to a bilinear ordinary differential equation of the form

$$i \frac{\partial}{\partial t}|\psi(t)\rangle = \left[H_0 + \sum_{k=1}^{m} u_k(t) H_k \right] |\psi(t)\rangle \quad (1)$$

where the functions $u_k(t)$ are the control variables and the H_k are corresponding control Hamiltonians, which are also assumed to be self-adjoint operators on the underlying Hilbert space. These models are used in the open loop control of closed quantum systems.

To represent open quantum systems, it is necessary to extend the notion of quantum state to density operators ρ which are positive operators with trace one on the underlying Hilbert space

$\mathcal{H}$. In this case, the Schrödinger picture model of a quantum system is given in terms of a master equation which describes the time evolution of the density operator. In the case of an open quantum system with Markovian dynamics defined on a finite dimensional Hilbert space of dimension N, the master equation is a matrix differential equation of the form

$$\dot{\rho}(t) = -i \left[\left(H_0 + \sum_{k=1}^{m} u_k(t) H_k \right), \rho(t) \right]$$
$$+ \frac{1}{2} \sum_{j,k=0}^{N^2-1} \alpha_{j,k} \left(\left[F_j \rho(t), F_k^\dagger \right] \right.$$
$$\left. + \left[F_j, \rho(t) F_k^\dagger \right] \right);$$
$$(2)$$

e.g., see Breuer and Petruccione (2002). Here the notation $[X, \rho] = X\rho - \rho X$ refers to the commutation operator and the notation † denotes the adjoint of an operator. Also, $\{F_j\}_{j=0}^{N^2-1}$ is a basis set for the space of bounded linear operators on $\mathcal{H}$ with $F_0 = I$. Also, the matrix $A = (\alpha_{j,k})$ is assumed to be positive definite. These models, which include the Lindblad master equation for dissipative quantum systems as a special case (e.g., see Wiseman and Milburn 2010), are used in the open loop control of finite-level Markovian open quantum systems.

In quantum mechanics, classical measurements are described in terms of self-adjoint operators on the underlying Hilbert space referred to as observables; e.g., see Breuer and Petruccione (2002). An important case of measurements are projective measurements in which an observable M is decomposed as $M = \sum_{k=1}^{m} k P_k$ where the P_k are orthogonal projection operators on $\mathcal{H}$; e.g., see Nielsen and Chuang (2000). Then, for a closed quantum system with quantum state $|\psi\rangle$, the probability of an outcome k from the measurement is given by $\langle \psi | P_k | \psi \rangle$ which denotes the inner product between the vector $|\psi\rangle$ and the vector $P_k |\psi\rangle$. This notation is referred to as Dirac notation and is commonly used in quantum mechanics. If the

outcome of the quantum measurement is k, the state of the quantum system collapses to the new value of $\frac{P_k|\psi\rangle}{\sqrt{\langle\psi|P_k|\psi\rangle}}$. This change in the quantum state as a result of a measurement is an important characteristic of quantum mechanics. For an open quantum system which is in a quantum state defined by a density operator ρ, the probability of a measurement outcome k is given by $\mathrm{tr}(P_k\rho)$. In this case, the quantum state collapses to $\frac{P_k\rho P_k}{\mathrm{tr}(P_k\rho)}$.

In the case of an open quantum system with continuous measurements of an observable X, we can consider a stochastic master equation as follows:

$$
\begin{aligned}
\mathrm{d}\rho(t) = &-i\left[\left(H_0 + \sum_{k=1}^{m} u_k(t)H_k\right),\rho(t)\right]\mathrm{d}t \\
&-\kappa\left[X,[X,\rho(t)]\right]\mathrm{d}t \\
&+\sqrt{2\kappa}\left(X\rho(t)+\rho(t)X\right. \\
&\left.-2\mathrm{tr}\left(X\rho(t)\right)\rho(t)\right)\mathrm{d}W
\end{aligned}
$$

$$(3)$$

where κ is a constant parameter related to the measurement strength and $\mathrm{d}W$ is a standard Wiener increment which is related to the continuous measurement outcome $y(t)$ by

$$
\mathrm{d}W = \mathrm{d}y - 2\sqrt{\kappa}\,\mathrm{tr}\left(X\rho(t)\right)\mathrm{d}t; \qquad (4)
$$

e.g., see Wiseman and Milburn (2010). These models are used in the measurement feedback control of Markovian open quantum systems. Also, the Eqs. (3) and (4) can be regarded as a quantum filter in which $\rho(t)$ is the conditional density of the quantum system obtained by filtering the measurement signal $y(t)$; e.g., see Bouten et al. (2007) and Gough et al. (2012).

Heisenberg Picture Models of Quantum Systems

In the Heisenberg picture of quantum mechanics, the observables of a system evolve with time and the quantum state remains fixed. This picture may also be extended slightly by considering the time evolution of general operators on the underlying Hilbert space rather than just observables which are required to be self-adjoint operators. An important class of open quantum systems which are considered in the Heisenberg picture arise when the underlying Hilbert space is infinite dimensional and the system represents a collection of independent quantum harmonic oscillators interacting with a number of external quantum fields. Such linear quantum systems are described in the Heisenberg picture by linear quantum stochastic differential equations (QSDEs) of the form

$$
\begin{aligned}
\mathrm{d}x(t) &= Ax(t)\mathrm{d}t + B\mathrm{d}w(t); \\
\mathrm{d}y(t) &= Cx(t)\mathrm{d}t + D\mathrm{d}w(t) \qquad (5)
\end{aligned}
$$

where A, B, C, D are real or complex matrices, $x(t)$ is a vector of possibly noncommuting operators on the underlying Hilbert space $\mathcal{H}$; e.g., see James et al. (2008). Also, the quantity $\mathrm{d}w(t)$ is decomposed as

$$
\mathrm{d}w(t) = \beta_w(t)\mathrm{d}t + \mathrm{d}\tilde{w}(t)
$$

where $\beta_w(t)$ is an adapted process and $\tilde{w}(t)$ is a quantum Wiener process with Itô table:

$$
\mathrm{d}\tilde{w}(t)\mathrm{d}\tilde{w}(t)^{\dagger} = F_{\tilde{w}}\mathrm{d}t.
$$

Here, $F_{\tilde{w}} \geq 0$ is a real or complex matrix. The quantity $w(t)$ represents the components of the input quantum fields acting on the system. Also, the quantity $y(t)$ represents the components of interest of the corresponding output fields that result from the interaction of the harmonic oscillators with the incoming fields.

In order to represent physical quantum systems, the components of vector $x(t)$ are required to satisfy certain commutation relations of the form

$$
\left[x_j(t), x_k(t)\right] = 2i\,\Theta_{jk}, \ \ j,k = 1, 2, \ldots, n, \ \forall t
$$

where the matrix $\Theta = \left(\Theta_{jk}\right)$ is skew symmetric. The requirement to represent a physical quantum system places restrictions on the matrices A, B, C, D, which are referred to as physical

realizability conditions; e.g., see James et al. (2008) and Shaiju and Petersen (2012). QSDE models of the form (5) arise frequently in the area of quantum optics. They can also be generalized to allow for nonlinear quantum systems such as arise in the areas of nonlinear quantum optics and superconducting quantum circuits; e.g., see Bertet et al. (2012). These models are used in the feedback control of quantum systems in both the case of classical measurement feedback and in the case of coherent feedback in which the quantum controller is also a quantum system and is represented by such a QSDE model.

(S, L, H) Quantum System Models

An alternative method of modeling an open quantum system as opposed to the stochastic master equation (SME) approach or the quantum stochastic differential equation (QSDE) approach, which were considered above, is to simply model the quantum system in terms of the physical quantities which underlie the SME and QSDE models. For a general open quantum system, these quantities are the *scattering matrix S* which is a matrix of operators on the underlying Hilbert space, the coupling operator L which is a vector of operators on the underlying Hilbert space, and the system Hamiltonian which is a self-adjoint operator on the underlying Hilbert space; e.g., see Gough and James (2009). For a given (S, L, H) model, the corresponding SME model or QSDE model can be calculated using standard formulas; e.g., see Bouten et al. (2007) and James et al. (2008). Also, in certain circumstances, an (S, L, H) model can be calculated from an SME model or a QSDE model. For example, if the linear QSDE model (5) is physically realizable, then a corresponding (S, L, H) model can be found. In fact, this amounts to the definition of physical realizability.

Open Loop Control of Quantum Systems

A fundamental question in the open loop control of quantum systems is the question of controllability. For the case of a closed quantum system of the form (1), the question of controllability can be defined as follows (e.g., see Albertini and D'Alessandro 2003):

Definition 1 (Pure State Controllability) The quantum system (1) is said to be *pure state controllable* if for every pair of initial and final states $|\psi_0\rangle$ and $|\psi_f\rangle$, there exist control functions $\{u_k(t)\}$ and a time $T > 0$ such that the corresponding solution of (1) with initial condition $|\psi_0\rangle$ satisfies $|\psi(T)\rangle = |\psi_f\rangle$.

Alternative definitions have also been considered for the controllability of the quantum system (1); e.g., see Albertini and D'Alessandro (2003) and Grigoriu et al. (2013) in the case of open quantum systems. The following theorem provides a necessary and sufficient condition for pure state controllability in terms of the Lie algebra $\mathcal{L}_0$ generated by the matrices $\{-iH_0, -iH_1, \ldots, -iH_m\}$, u$(N)$ the Lie algebra corresponding to the unitary group of dimension N, su(N) the Lie algebra corresponding to the special unitary group of dimension N, sp$(\frac{N}{2})$ the $\frac{N}{2}$ dimensional symplectic group, and $\tilde{\mathcal{L}}$ the Lie algebra conjugate to sp$(\frac{N}{2})$.

Theorem 1 (See D'Alessandro 2007) *The quantum system (1) is pure state controllable if and only if the Lie algebra $\mathcal{L}_0$ satisfies one of the following conditions:*
(1) $\mathcal{L}_0 = $ su(N);
(2) $\mathcal{L}_0$ is conjugate to sp$(\frac{N}{2})$;
(3) $\mathcal{L}_0 = $ u(N);
(4) $\mathcal{L}_0 = $ span $\{i I_{N \times N}\} \oplus \tilde{\mathcal{L}}$.

Similar conditions have been obtained when alternative definitions of controllability are used.

Once it has been determined that a quantum system is controllable, the next task in open loop quantum control is to determine the control functions $\{u_k(t)\}$ which drive a given initial state to a given final state. An important approach to this problem is the optimal control approach in which a time optimal control problem is solved using Pontryagin's maximum principle to construct the control functions $\{u_k(t)\}$ which drives the given initial state to the given final state in minimum time; e.g., see Khaneja et al. (2001).

This approach works well for low dimensional quantum systems but is computationally intractable for high dimensional quantum systems.

An alternative approach for high dimensional quantum systems is the Lyapunov control approach. In this approach, a Lyapunov function is selected which provides a measure of the distance between the current quantum state and the desired terminal quantum state. An example of such a Lyapunov function is

$$V = \langle \psi(t) - \psi_f | \psi(t) - \psi_f \rangle \geq 0;$$

e.g., see Mirrahimi et al. (2005). A state feedback control law is then chosen to ensure that the time derivative of this Lyapunov function is negative. This state feedback control law is then simulated with the quantum system dynamics (1) to give the required open loop control functions $\{u_k(t)\}$.

Classical Measurement Based Quantum Feedback Control

A Schrödinger Picture Approach to Classical Measurement Based Quantum Feedback Control

In the Schrödinger picture approach to classical measurement based quantum feedback control with weak continuous measurements, we begin the stochastic master equations (3) and (4) which are considered as both a model for the system being controlled and as a filter which will form part of the final controller. These filter equations are then combined with a control law of the form

$$u(t) = f(\rho(t))$$

where the function $f(\cdot)$ is designed to achieve a particular objective such as stabilization of the quantum system. Here $u(t)$ represents the vector of control inputs $u_k(t)$. An example of such a quantum control scheme is given in the paper Mirrahimi and van Handel (2007) in which a Lyapunov method is used to design the control law $f(\cdot)$ so that a quantum system consisting of an atomic ensemble interacting with an

electromagnetic field is stabilized about a specified state $\rho_f = |\psi_m\rangle\langle\psi_m|$.

A Heisenberg Picture Approach to Classical Measurement Based Quantum Feedback Control

In this Heisenberg picture approach to classical measurement based quantum feedback control, we begin with a quantum system which is described by linear quantum stochastic equations of the form (5). In these equations, it is assumed that the components of the output vector all commute with each other and so can be regarded as classical quantities. This can be achieved if each of the components are obtained via a process of homodyne detection from the corresponding electromagnetic field; e.g., see Bachor and Ralph (2004). Also, it is assumed that the input electromagnetic field $w(t)$ can be decomposed as

$$dw(t) = \begin{bmatrix} \beta_u(t)dt + d\tilde{w}_1(t) \\ dw_2(t) \end{bmatrix} \qquad (6)$$

where $\beta_u(t)$ represents the classical control input signal and $\tilde{w}_1(t)$, $w_2(t)$ are quantum Wiener processes. The control signal displaces components of the incoming electromagnetic field acting on the system via the use of an electro-optic modulator; e.g., see Bachor and Ralph (2004).

The classical measurement feedback based controllers to be considered are classical systems described by stochastic differential equations of the form

$$dx_K(t) = A_K x_k(t)dt + B_K dy(t)$$
$$\beta_u(t)dt = C_K x_k(t)dt. \qquad (7)$$

For a given quantum system model (5), the matrices in the controller (7) can be designed using standard classical control theory techniques such as LQG control (see Doherty and Jacobs 1999) or H^∞ control (see James et al. 2008).

Coherent Quantum Feedback Control

Coherent feedback control of a quantum system corresponds to the case in which the controller itself is a quantum system which is coupled in a feedback interconnection to the quantum system being controlled; e.g., see Lloyd (2000). This type of control by interconnection is closely related to the behavioral interpretation of feedback control; e.g., see Polderman and Willems (1998).

An important approach to coherent quantum feedback control occurs in the case when the quantum system to be controlled is a linear quantum system described by the QSDEs (5). Also, it is assumed that the input field is decomposed as in (6). However in this case, the quantity $\beta_u(t)$ represents a vector of noncommuting operators on the Hilbert space underlying the controller system. These operators are described by the following linear QSDEs, which represent the quantum controller:

$$dx_K(t) = A_K x_k(t)dt + B_K dy(t) + \bar{B}_K d\bar{w}_K(t)$$
$$dy_K(t) = C_K x_k(t)dt + \bar{D}_K d\bar{w}_K(t). \qquad (8)$$

Then, the input $\beta_u(t)$ is identified as

$$\beta_u(t) = C_K x_k(t).$$

Here the quantity

$$dw_K(t) = \begin{bmatrix} dy(t) \\ d\bar{w}_K(t) \end{bmatrix} \qquad (9)$$

represents the quantum fields acting on the controller quantum system and where $w_K(t)$ corresponds to a quantum Wiener process with a given Itô table. Also, $y(t)$ represents the output quantum fields from the quantum system being controlled. Note that in the case of coherent quantum feedback control, there is no requirement that the components of $y(t)$ commute with each other and this in fact represents one of the main advantages of coherent quantum feedback control as opposed to classical measurement based quantum feedback control.

An important requirement in coherent feedback control is that the QSDEs (8) should satisfy the conditions for physical realizability; e.g., see James et al. (2008). Subject to these constraints, the controller (8) can then be designed according to an H^∞ or LQG criterion; e.g., see James et al. (2008) and Nurdin et al. (2009). In the case of coherent quantum H^∞ control, it is shown in James et al. (2008) that for any controller matrices (A_K, B_K, C_K), the matrices $(\bar{B}_K, \bar{D}_K)$ can be chosen so that the controller QSDEs (8) are physically realizable. Furthermore, the choice of the matrices $(\bar{B}_K, \bar{D}_K)$ does not affect the H^∞ performance criterion considered in James et al. (2008). This means that the coherent controller can be designed using the same approach as designing a classical H^∞ controller.

In the case of coherent LQG control such as considered in Nurdin et al. (2009), the choice of the matrices $(\bar{B}_K, \bar{D}_K)$ significantly affects the closed loop LQG performance of the quantum control system. This means that the approach used in solving the coherent quantum H^∞ problem given in James et al. (2008) cannot be applied to the coherent quantum LQG problem. To date there exist only some nonconvex optimization methods which have been applied to the coherent quantum LQG problem (e.g., see Nurdin et al. 2009), and the general solution to the coherent quantum LQG control problem remains an open question.

Abstract

The undesirable effects of roll motion of ships (rocking about the longitudinal axis) became noticeable in the mid-nineteenth century when significant changes were introduced to the design of ships as a result of sails being replaced by steam engines and the arrangement being changed from broad to narrow hulls. The combination of these changes led to lower transverse stability (lower restoring moment for a given angle of roll) with the consequence of larger roll motion. The increase in roll motion and its effect on cargo and human performance lead to the development several control devices that aimed at reducing and controlling roll motion. The control devices most commonly used today are fin stabilizers, rudder, anti-roll tanks, and gyrostabilizers. The use of

different types of actuators for control of ship roll motion has been amply demonstrated for over 100 years. Performance, however, can still fall short of expectations because of difficulties associated with control system design, which have proven to be far from trivial due to fundamental performance limitations and large variations of the spectral characteristics of wave-induced roll motion. This short article provides an overview of the fundamentals of control design for ship roll motion reduction. The overview is limited to the most common control devices. Most of the material is based on Perez (Ship motion control. Advances in industrial control. Springer, London, 2005) and Perez and Blanke (Ann Rev Control 36(1):1367–5788, 2012).

Keywords

Roll damping; Ship motion control

Ship Roll Motion Control Techniques

One of the most commonly used devices to attenuate ship motion are the fin stabilisers. These are small controllable fins located on the bilge of the hull usually amid ships. These devices attain a performance in the range of 60–90 % of roll reduction (root mean square) (Sellars and Martin 1992). They require control systems that sense the vessel's roll motion and act by changing the angle of the fins. These devices are expensive and introduce underwater noise that can affect sonar performance, they add to propulsion losses, and they can be damaged. Despite this, they are among the most commonly used ship roll motion control device. From a control perspective, highly nonlinear effects (dynamic stall) may appear when operating in severe sea states and heavy rolling conditions (Gaillarde 2002).

During studies of ship damage stability conducted in the late 1800s, it was observed that under certain conditions the water inside the vessel moved out of phase with respect to the wave profile, and thus, the weight of the water on the vessel counteracted the increase of pressure on the hull, hence reducing the net roll excitation moment. This led to the development of fluid anti-roll tank stabilizers. The most common type of anti-roll tank is the U-tank, which comprises two reservoirs, located one on port and one on starboard, connected at the bottom by a duct. Anti-roll tanks can be either passive or active. In passive tanks, the fluid flows freely from side to side. According to the density and viscosity of the fluid used, the tank is dimensioned so that the time required for most of the fluid to flow from side to side equals the natural roll period of the ship. Active tanks operate in a similar manner, but they incorporate a control system that modifies the natural period of the tank to match the actual ship roll period. This is normally achieved by controlling the flow of air from the top of one reservoir to the other. Anti-roll tanks attain a medium to high performance in the range of 20–70 % of roll angle reduction (RMS) (Marzouk and Nayfeh 2009). Anti-roll tanks increase the ship displacement. They can also be used to correct list (steady-state roll angle), and they are the preferred stabilizer for icebreakers.

Rudder-roll stabilization (RRS) is a technique based on the fact that the rudder is located not only aft, but also below the center of gravity of the vessel, and thus the rudder imparts not only yaw but also roll moment. The idea of using the rudder for simultaneous course keeping and roll reduction was conceived in the late 1960s by observations of anomalous behavior of autopilots that did not have appropriate wave filtering – a feature of the autopilot that prevents the rudder from reacting to every single wave; see, for example, Fossen and Perez (2009) for a discussion on wave filtering. Rudder-roll stabilization has been demonstrated to attain medium to high performance in the range of 50–75 % of roll reduction (RMS) (Baitis et al. 1983; Blanke et al. 1989; Källström et al. 1988; Oda et al. 1992; van Amerongen et al. 1990). The upgrade of the rudder machinery is required to be able to attain slew rates in the range 10–20 deg/s for RRS to have sufficient control authority.

A gyrostabilizer uses the gyroscopic effects of large rotating wheels to generate a roll reducing torque. The use of gyroscopic effects was

proposed in the early 1900s as a method to eliminate roll, rather than to reduce it. Although the performance of these systems was remarkable, up to 95 % roll reduction, their high cost, the increase in weight, and the large stress produced on the hull masked their benefits and prevented further developments. However, a recent increase in development of gyrostabilizers has been seen in the yacht industry (Perez and Steinmann 2009).

Fins and rudder give rise to lift forces in proportion to the square of flow velocity past the fin. Hence, roll stabilization by fin or rudder is not possible at low or zero speed. Only U-tanks and gyro devices are able to provide stabilization in these conditions. For further details about the performance of different devices, see Sellars and Martin (1992), and for a comprehensive description of the early development of devices, see Chalmers (1931).

Modeling of Ship Roll Motion for Control Design

The study of roll motion dynamics for control system design is normally done in terms of either one- or four-degrees-of-freedom (DOF) models. The choice between models of different complexity depends on the type of motion control system considered.

For a one-degree-of-freedom (1DOF) case, the following model is used:

$$\dot{\phi} = p, \tag{1}$$

$$I_{xx} \dot{p} = K_h + K_w + K_c, \tag{2}$$

where ϕ is roll angle, p is roll rate, and I_{xx} is rigid-body moment of inertia about the x-axis of a body-fixed coordinate system, where K_h is hydrostatic and hydrodynamic torques, K_w torque generated by wave forces acting on the hull, and K_c the control torques. The hydrodynamic torque can be approximated by the following parametric model: $K_h \approx K_{\dot{p}} \dot{p} + K_p p + K_{p|p|} p|p| + K(\phi)$. The first term represents a hydrodynamic torque in roll due to pressure change that is proportional to the roll accelerations, and the coefficient $K_{\dot{p}}$

is called roll added mass (inertia). The second term is a damping term, which captures forces due to wave making and linear skin friction, and the coefficient K_p is a linear damping coefficient. The third term is a nonlinear damping term, which captures forces due to viscous effects. The last term is the restoring torque due to gravity and buoyancy.

For a 4DOF model (surge, sway, roll, and yaw), motion variables considered are $\boldsymbol{\eta} = [\phi \ \psi]^\mathsf{T}$, $\boldsymbol{\nu} = [u \ v \ p \ r]^\mathsf{T}$, $\boldsymbol{\tau}_i = [X \ Y \ K \ N]^\mathsf{T}$, where ψ is the yaw angle, the body-fixed velocities are u-surge and v-sway, and r is the yaw rate. The forces and torques are X-surge, Y-sway, K-roll, and N-yaw. With these variables, the following mathematical model is usually considered:

$$\dot{\boldsymbol{\eta}} = \mathbf{J}(\boldsymbol{\eta}) \, \boldsymbol{\nu}, \tag{3}$$

$$\mathbf{M}_{RB} \, \dot{\boldsymbol{\nu}} + \mathbf{C}_{RB}(\boldsymbol{\nu})\boldsymbol{\nu} = \boldsymbol{\tau}_h + \boldsymbol{\tau}_c + \boldsymbol{\tau}_d, \tag{4}$$

where $\mathbf{J}(\boldsymbol{\eta})$ is a kinematic transformation, $\mathbf{M}_{RB}$ is the rigid-body inertia matrix that corresponds to expressing the inertia tensor in body-fixed coordinates, $\mathbf{C}_{RB}(\boldsymbol{\nu})$ is the rigid-body Coriolis and centripetal matrix, and $\boldsymbol{\tau}_h$, $\boldsymbol{\tau}_c$, and $\boldsymbol{\tau}_d$ represent the hydrodynamic, control, and disturbance vector of force components and torques, respectively.

The hydrostatic and hydrodynamic forces are $\boldsymbol{\tau}_h \approx -\mathbf{M}_A \, \dot{\boldsymbol{\nu}} - \mathbf{C}_A(\boldsymbol{\nu})\boldsymbol{\nu} - \mathbf{D}(\boldsymbol{\nu})\boldsymbol{\nu} - \mathbf{K}(\phi)$. The first two terms have origin in the motion of a vessel in an irrotational flow in a nonviscous fluid. The third term corresponds to damping forces due to potential (wave making), skin friction, vortex shedding, and circulation (lift and drag). The hydrodynamic effects involved are quite complex, and different approaches based on superposition of either odd-term Taylor expansions or square modulus ($x|x|$) series expansions are usually considered Abkowitz (1964) and Fedyaevsky and Sobolev (1964). The $\mathbf{K}(\phi)$ term represents the restoring forces in roll due to buoyancy and gravity. The 4DOF model captures parameter dependency on ship speed as well as the couplings between steering and roll, and it is useful for controller design. For additional details about mathematical model of marine vehicles, see Fossen (2011).

Wave-Disturbance Models

The action of the waves creates changes in pressure on the hull of the ship, which translate into forces and moments. It is common to model the ship motion response due to waves within a linear framework and to obtain two frequency-response functions (FRF), wave to excitation $F_i(j\omega, U, \chi)$ and wave to motion $H_i(j\omega, U, \chi)$ response functions, where i indicates the degree of freedom. These FRF depend on the wave frequency, the ship speed, and the angle χ at which the waves encounter the ship – this is called the encounter angle.

The wave elevation in deep water is approximately a stochastic process that is zero mean, stationary for short periods of time, and Gaussian (Haverre and Moan 1985). Under these assumptions, the wave elevation ζ is fully described by a power spectral density $\Phi_{\zeta\zeta}(\omega)$. With a linear response assumption, the power spectral density of wave to excitation force and wave to motion can be expressed as

$$\Phi_{FF,i}(j\omega) = |F_i(j\omega, U, \chi)|^2 \Phi_{\zeta\zeta}(j\omega),$$

$$\Phi_{\eta\eta,i}(j\omega) = |H_i(j\omega, U, \chi)|^2 \Phi_{\zeta\zeta}(j\omega).$$

These spectra are models of the wave-induced forces and motions, respectively, from which it its common to generate either time series of wave excitation forces in terms of the encounter frequency to be used as input disturbances in simulation models or time series of wave-induced motion to be used as output disturbance; see, for example, Perez (2005) and references herein.

Roll Motion Control and Performance Limitations

The analysis of performance of ship roll motion control by means of force actuators is usually conducted within a linear framework by linearizing the models. For a SISO loop where the wave-induced roll motion is considered an output disturbance, the Bode integral constraint applies. This imposes restrictions on one's freedom to shape the closed-loop transfer function

to attenuate the motion due to the wave-induced forces in different frequency ranges. These results have important consequences on the design of a roll motion control system since the frequency of the waves seen from the vessel changes significantly with the sea state, the speed of the vessel, and the wave encounter angle. The changing characteristics on open-loop roll motion in conjunction with the Bode integral constraint make the control design challenging since roll amplification may occur if the control design is not done properly. For some roll motion control problems, like using the rudder for simultaneous roll attenuation and heading control, the system presents non-minimum phase dynamics. In this case, the trade-off of reduced sensitivity *vs.* amplification of roll motion is dominating at frequencies close to the non-minimum phase zero – a constraint with origin in the Poisson integral (Hearns and Blanke 1998); see also Perez (2005).

It should be noted that non-minimum phase dynamics also occurs with fin stabilizers, when the stabilizers are located aft of the center of gravity. With the fins at this location, they behave like a rudder and introduce non-minimum phase dynamics and heading interference at low wave-excitation frequencies. These aspects of fin location were discussed by Lloyd (1989).

The above discussion highlights general design constraints that apply to roll motion control systems in terms of the dynamics of the vessel and actuator. In addition to these constraints, one needs also to account for limitations in actuator slew rate and angle.

Controls Techniques Used in Different Roll Control Systems

Fin Stabilizers

In regard to fin stabilizers, the control design is commonly address using the 1DOF model (1) and (2). The main issues associated with control design are the parametric uncertainty in model and the Bode integral constraint. This integral constraint can lead to roll amplification due to changes in the spectrum of the wave-induced

roll moment with sea state and sailing conditions (speed and encounter angle). Fin machinery is designed so that the rate of the fin motion is fast enough, and actuator rate saturation is not an issue in moderate sea states. The fins could be used to correct heeling angles (steady-state roll) when the ship makes speed, but this is avoided due to added resistance. If it is used, integral action needs to include anti-windup. In terms of control strategies, PID, $\mathcal{H}_\infty$, and LQR techniques have been successfully applied in practice. Highly nonlinear effects (dynamic stall) may appear when operating in severe sea states and heavy rolling conditions, and proposals for applications of model predictive control have been put forward to constraint the effective angle of attack of the fins. In addition, if the fins are located too far aft along the ship, the dynamic response from fin angle to roll can exhibit non-minimum phase dynamics, which can limit the performance at low encounter frequencies. A thorough review of the control literature can be found in Perez and Blanke (2012).

Rudder-Roll Stabilization

The problem of rudder-roll stabilization requires the 4DOF model (3) and (4), which captures the interaction between roll, sway, and yaw together with the changes in the hydrodynamic forces due to the forward speed. The response from rudder to roll is non-minimum phase (NMP), and the system is characterized by further constraints due to the single-input-two-output nature of the control problem – attenuate roll without too much interference with the heading. Studies of fundamental limitations due to NMP dynamics have been approached using standard frequency-domain tools by Hearns and Blanke (1998) and Perez (2005). A characterization of the trade-off between roll reduction vs. increase of interference was part of the controller design in Stoustrup et al. (1994). Perez (2005) determined the limits obtainable using optimal control with full disturbance information. The latter also incorporated constraints due to the limiting authority of the control action in rate and magnitude of rudder machinery and stall conditions of the rudder. The control design for rudder-roll stabilization

has been addressed in practice using PID, LQG, and $\mathcal{H}_\infty$ and standard frequency-domain linear control designs. The characteristics of limited control authority were solved by van Amerongen et al. (1990) using automatic gain control. In the literature, there have been proposals put forward for the use of model predictive control, QFT, sliding-mode nonlinear control, and auto-regressive stochastic control. Combined use of fin and rudder has also be investigated. Grimble et al. (1993) and later Roberts et al. (1997) used $\mathcal{H}_\infty$ control techniques. Thorough comparison of controller performances for warships was published in Crossland (2003). A thorough review of the control literature can be found in Perez and Blanke (2012).

Gyrostabilizers

Using a single gimbal suspension gyrostabilizer for roll damping control, the coupled vessel-roll-gyro model can be modeled as follows:

$$\dot{\phi} = p, \tag{5}$$

$$K_{\dot{p}}\,\dot{p} + K_p\,p + K_\phi\,\phi = K_w - K_g\dot{\alpha}\cos\alpha \tag{6}$$

$$I_p\ddot{\alpha} + B_p\dot{\alpha} + C_p\sin\alpha = K_g\,p\cos\alpha + T_p, \tag{7}$$

where (6) represents the 1DOF roll dynamics and (7) represents the dynamics of the gyrostabilizer about the axis of the gimbal suspension, where α is the gimbal angle, equivalent to the precession angle for a single gimbal suspension, I_p is gimbal and wheel inertia about the gimbal axis, B_p is the damping, and C_p is a restoring term of the gyro about the precession axis due to location of the gyro center of mass relative to the precession axis (Arnold and Maunder 1961). T_p is the control torque applied to the gimbal. The use of twin counter-spinning wheels prevents gyroscopic coupling with other degrees of freedom. Hence, the control design for gyrostabilizers can be based on a linear single-degree-of-freedom model for roll.

The wave-induced roll moment K_w excites the roll motion. As the roll motion develops, the roll rate p induces a torque along the precession axis of the gyrostabilizer. As the precession angle α

develops, there is reaction torque done on the vessel that opposes the wave-induced moment. The later is the roll stabilizing torque, $X_g \triangleq -K_g \dot{\alpha} \cos \alpha \approx -K_g \dot{\alpha}$. This roll torque can only be controlled indirectly through the precession dynamics in (7) via T_p. In the model above, the spin angular velocity ω_{spin} is controlled to be constant; hence the wheels' angular momentum $K_g = I_{spin} \omega_{spin}$ is constant.

The precession control torque T_p is used to control the gyro. As observed by Sperry (Chalmers 1931), the intrinsic behavior of the gyrostabilizer is to use roll rate to generate a roll torque. Hence, one could design a precession torque controller such that from the point of view of the vessel, the gyro behaves as damper. Depending on how precession torque is delivered, it may be necessary to constraint precession angle and rate. This problem has been recently considered in Donaire and Perez (2013) using passivity-based control.

U-tanks

U-tanks can be passive or active. Roll reduction is achieved by attempting to transfer energy from the roll motion to motion of liquid within the tank and using the weight of the liquid to counteract the wave excitation moment. A key aspect of the design is the dimension and geometry of the tank to ensure that there is enough weight due to the displaced liquid in the tank and that the oscillation of the fluid in the tank matches the vessel natural frequency in roll; see Holden and Fossen (2012) and references herein. The design of the U-tank can ensure a single-frequency matching, at which the performance is optimized, and for this frequency the roll natural frequency is used. As the frequency of roll motion departs from this, a degradation of roll reduction occurs. Active U-tanks use valves to control the flow of air from the top of the reservoirs to extend the frequency matching in sailing conditions in which the roll dominant frequency is lower than the roll natural frequency – the flow of air is used to delay the motion of the liquid from one reservoir to the other. This control is achieved by detecting the dominant roll frequency and using this information to control the air flow from one reservoir

to the other. If the roll dominant frequency is higher than the roll natural frequency, the U-tank is used in passive mode, and the standard roll reduction degradation occurs.

Summary and Future Directions

This article provides a brief summary of control aspects for the most common ship roll motion control devices. These aspects include the type of mathematical models used to design and analyze the control problem, the inherent fundamental limitations and the constraints that some of the designs are subjected to, and the performance that can be expected from the different devices. As an outlook, one of the key issues in roll motion control is the model uncertainty and the adaptation to the changes in the environmental conditions. As the vessel changes speed and heading, or as the seas build up or abate, the dominant frequency range of the wave-induced forces changes significantly. Due to the fundamental limitations discussed, a nonadaptive controller may produce roll amplification rather than roll reduction. This topic has received some attention in the literature via multi-mode control switching, but further work in this area could be beneficial. In the recent years, new devices have appeared for stabilization at zero speed, like flapping fins and rotating cylinders. Also the industry's interest in roll gyrostabilizers has been re-ignited. The investigation of control designs for these devices has not yet received much attention within the control community. Hence, it is expected that this will create a potential for research activity in the future.

Control Structure Selection

Sigurd Skogestad
Department of Chemical Engineering,
Norwegian University of Science and
Technology (NTNU), Trondheim, Norway

Abstract

Control structure selection deals with selecting what to control (outputs), what to measure and what to manipulate (inputs), and also how to split the controller in a hierarchical and decentralized manner. The most important issue is probably the selection of the controlled variables (outputs), CV = Hy, where y are the available measurements and H is a degree of freedom that is seldom treated in a systematic manner by control engineers. This entry discusses how to find H for both for the upper (slower) economic layer and the lower (faster) regulatory layer in the control hierarchy. Each layer may be split in a decentralized fashion. Systematic approaches for input/output (IO) selection are presented.

Keywords

Control configuration; Control hierarchy; Control structure design; Decentralized control;

Economic control; Input-output controllability; Input/output selection; Plantwide control; Regulatory control; Supervisory control

Introduction

Consider the generalized controller design problem in Fig. 1 where P denotes the generalized plant model. Here, the objective is to design the controller K, which, based on the sensed outputs v, computes the inputs (MVs) u such that the variables z are kept small, in spite of variations in the variables w, which include disturbances (d), varying setpoints/references (CV_s) and measurement noise (n),

$$w = [d, CV_s, n]$$

The variables z, which should be kept small, typically include the control error for the selected controlled variables (CV) plus the plant inputs (u),

$$z = [CV - CV_s; u]$$

The variables v, which are the inputs to the controller, include all known variables, including measured outputs (y_m), measured disturbances (d_m) and setpoints,

$$v = [y_m; d_m; CV_s].$$

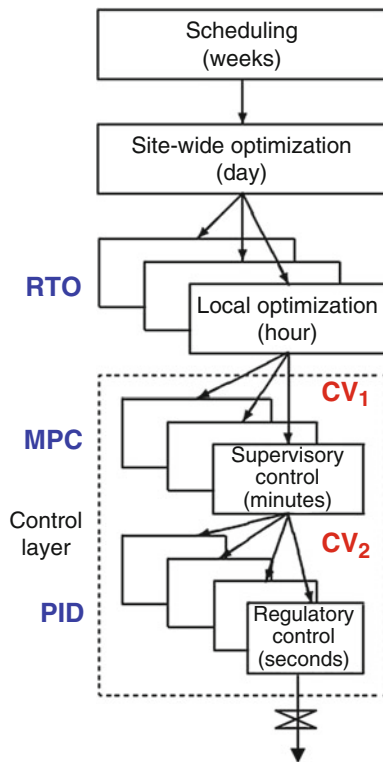
The cost function for designing the optimal controller K is usually the weighted control error,
Control Structure Selection, Fig. 1 General formulation for designing the controller K. The plant P is controlled by manipulating u, and is disturbed by the signals w. The controller uses the measurements v, and the control objective is to keep the outputs (weighted control error) z as small as possible

$J' = ||W'z||$. The reason for using a prime on J (J'), is to distinguish it from the economic cost J which we later use for selecting the controlled variables (CV).

Notice that it is assumed in Fig. 1 that we know what to measure (v), manipulate (u), and, most importantly, which variables in z we would like to keep at setpoints (CV), that is, we have assumed a given control structure. The term "control structure selection" (CSS) and its synonym "control structure design" (CSD) is associated with the overall *control philosophy* for the system with emphasis on the **structural decisions** which are a prerequisite for the controller design problem in Fig. 1:

1. *Selection of controlled variables (CVs, "outputs," included in z in Fig. 1)*
2. *Selection of manipulated variables (MVs, "inputs," u in Fig. 1)*
3. *Selection of measurements y (included in v in Fig. 1)*
4. *Selection of control **configuration** (structure of overall controller K that interconnects the controlled, manipulated and measured variables; structure of K in Fig. 1)*
5. *Selection of type of controller K (PID, MPC, LQG, H-infinity, etc.) and objective function (norm) used to design and analyze it.*

Decisions 2 and 3 (selection of u and y) are sometimes referred to as the input/output (IO) selection problem. In practice, the controller (K) is usually divided into several layers, operating on different time scales (see Fig. 2), which implies that we in addition to selecting the (primary) controlled variables ($CV_1 \equiv CV$) must also select the (secondary) variables that interconnect the layers (CV_2).

Control structure selection includes all the *structural* decisions that the engineer needs to make when designing a control system, but it does not involve the actual design of each individual controller block. Thus, it involves the decisions necessary to make a block diagram (Fig. 1; used by control engineers) or process & instrumentation diagram (used by process engineers) for the entire plant, and provides the starting point for a detailed controller design.


Control Structure Selection, Fig. 2 Typical control hierarchy, as illustrated for a process plant

The term "plantwide control," which is a synonym for "control structure selection," is used in the field of process control. Control structure selection is particularly important for process control because of the complexity of large processing plants, but it applies to all control applications, including vehicle control, aircraft control, robotics, power systems, biological systems, social systems, and so on.

It may be argued that control structure selection is more important than the controller design itself. Yet, control structure selection is hardly covered in most control courses. This is probably related to the complexity of the problem, which requires the knowledge from several engineering fields. In the mathematical sense, the control structure selection problem is a formidable combinatorial problem which involves a large number of discrete decision variables.

Overall Objectives for Control and Structure of the Control Layer

The starting point for control system design is to define clearly the operational objectives. There are usually two main objectives for control:

1. Longer-term economic operation (minimize economic cost J subject to satisfying operational constraints)
2. Stability and short-term regulatory control

The first objective is related to "making the system operate as intended," where economics are an important issue. Traditionally, control engineers have not been much involved in this step. The second objective is related to "making sure the system stays operational," where stability and robustness are important issues, and this has traditionally been the main domain of control engineers. In terms of designing the control system, the second objective (stabilization) is usually considered first. An example is bicycle riding; we first need to learn how to stabilize the bicycle (regulation), before trying to use it for something useful (optimal operation), like riding to work and selecting the shortest path.

We use the term "economic cost," because usually the cost function J can be given a monetary value, but more generally, the cost J could be any scalar cost. For example, the cost J could be the "environmental impact" and the economics could then be given as constraints.

In theory, the optimal strategy is to combine the control tasks of optimal economic operation and stabilization/regulation in a single centralized controller K, which at each time step collects all the information and computes the optimal input changes. In practice, simpler controllers are used. The main reason for this is that in most cases one can obtain acceptable control performance with simple structures, where each controller block involves only a few variables. Such control systems can be designed and tuned with much less effort, especially when it comes to the modeling and tuning effort.

So how are large-scale systems controlled in practise? Usually, the controller K is decomposed

into several subcontrollers, using two main principles

– *Decentralized (local) control.* This "horizontal decomposition" of the control layer is usually based on separation in space, for example, by using local control of individual units.
– *Hierarchical (cascade) control.* This "vertical decomposition" is usually based on time scale separation, as illustrated for a process plant in Fig. 2. The upper three layers in Fig. 2 deal explicitly with economic optimization and are not considered here. We are concerned with the two lower *control layers,* where the main objective is to track the setpoints specified by the layer above.

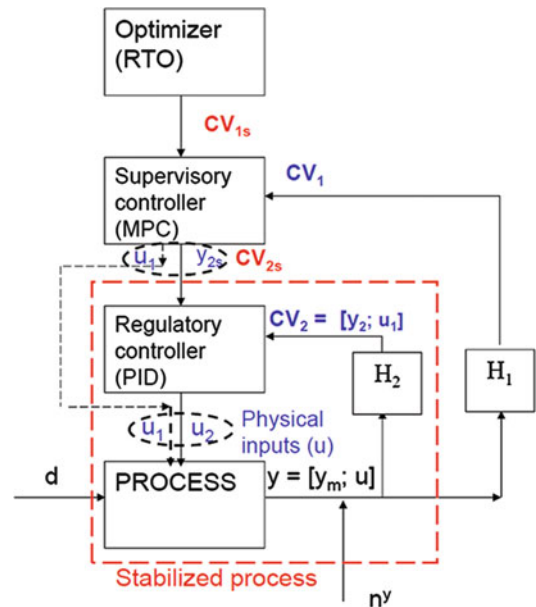
In accordance with the two main objectives for control, the control layer is in most cases divided hierarchically in two layers (Fig. 2):

1. A "slow" supervisory (economic) layer
2. A "fast" regulatory (stabilization) layer

Another reason for the separation in two control layers, is that the tasks of economic operation and regulation are fundamentally different. Combining the two objectives in a single cost function, which is required for designing a single centralized controller K, is like trying to compare apples and oranges. For example, how much is an increased stability margin worth in monitory units [$]? Only if there is a reasonable benefit in combining the two layers, for example, because there is limited time scale separation between the tasks of regulation and optimal economics, should one consider combining them into a single controller.

Notation and Matrices H_1 and H_2 for Controlled Variable Selection

The most important notation is summarized in Table 1 and Fig. 3. To distinguish between the two control layers, we use "1" for the upper supervisory (economic) layer and "2" for the regulatory layer, which is "secondary" in terms of its place in the control hierarchy.

There is often limited possibility to select the input set (u) as it is usually constrained by the


Control Structure Selection, Fig. 3 Block diagram of a typical control hierarchy, emphasizing the selection of controlled variables for supervisory (economic) control ($CV_1 = H_1 y$) and regulatory control ($CV_2 = H_2 y$)

Control Structure Selection, Table 1 Important notation

$u = [u_1; u_2]$ = set of all available physical plant inputs
u_1 = inputs used directly by supervisory control layer
u_2 = inputs used by regulatory layer
y_m = set of all measured outputs
$y = [y_m; u]$ = combined set of measurements and inputs
y_2 = controlled outputs in regulatory layer (subset or combination of y); $\dim(y_2) = \dim(u_2)$
$CV_1 = H_1 y$ = controlled variables in supervisory layer; $\dim(CV_1) = \dim(u)$
$CV_2 = [y_2; u_1] = H_2 y$ = controlled variables in regulatory layer; $\dim(CV_2) = \dim(u)$
$MV_1 = CV_{2s} = [y_{2s}; u_1]$ = manipulated variables in supervisory layer; $\dim(MV_1) = \dim(u)$
$MV_2 = u_2$ = manipulated variables in regulatory layer; $\dim(MV_2) = \dim(u_2) \leq \dim(u)$

plant design. However, there may be a possibility to add inputs or to move some to another location, for example, to avoid saturation or to reduce the time delay and thus improve the input-output controllability.

There is much more flexibility in terms of output selection, and the most important structural decision is related to the selection of controlled variables in the two control layers, as given by the decision matrices H_1 and H_2 (see Fig. 3).

$$CV_1 = H_1 y$$
$$CV_2 = H_2 y$$

Note from the definition in Table 1 that $y = [y_m; u]$. Thus, y includes, in addition to the candidate measured outputs (y_m), also the physical inputs u. This allows for the possibility of selecting an input u as a "controlled" variable, which means that this input is kept constant (or, more precisely, the input is left "unused" for control in this layer).

In general, H_1 and H_2 are "full" matrices, allowing for measurement combinations as controlled variables. However, for simplicity, especially in the regulatory layer, we often pefer to control individual measurements, that is, H_2 is usually a "selection matrix," where each row in H_2 contains one 1-element (to identify the selected variable) with the remaining elements set to 0. In this case, we can write $CV_2 = H_2 y = [y_2; u_1]$, where y_2 denotes the actual controlled variables in the regulatory layer, whereas u_1 denotes the "unused" inputs (u_1), which are left as degrees of freedom for the supervisory layer. Note that this indirectly determines the inputs u_2 used in the regulatory layer to control y_2, because u_2 is what remains in the set u after selecting u_1. To have a simple control structure, with as few regulatory loops as possible, it is desirable that H_2 is selected such that there are many inputs (u_1) left "unused" in the regulatory layer.

Example. Assume there are three candidate output measurements (temperatures T) and two inputs (flowrates q),

$$y_m = [T_a T_b T_c] , \quad u = [q_a q_b]$$

and we have by definition $y = [y_m; u]$. Then the choice

$$H_2 = [0\ 1\ 0\ 0\ 0; \ 0\ 0\ 0\ 0\ 1]$$

means that we have selected $CV_2 = H_2 y = [T_b; q_b]$. Thus, $u_1 = q_b$ is an unused input for regulatory control, and in the regulatory layer we close one loop, using $u_2 = q_a$ to control $y_2 = T_b$. If we instead select

$$H_2 = [1\ 0\ 0\ 0\ 0; \ 0\ 0\ 1\ 0\ 0]$$

then we have $CV_2 = [T_a; T_c]$. None of these are inputs, so u_1 is an empty set in this case. This means that we need to close two regulatory loops, using $u_2 = [q_a; q_b]$ to control $y_2 = [T_a; T_c]$.

Supervisory Control Layer and Selection of Economic Controlled Variables (CV_1)

Some objectives for the supervisory control layer are given in Table 2. The main structural issue for the supervisory control layer, and probably the most important decision in the design of any control system, is the selection of the primary (economic) controlled variable CV_1. In many cases, a good engineer can make a reasonable choice based on process insight and experience. However, the control engineer must realize that this is a critical decision. The main rules and issues for selecting CV_1 are

CV_1 Rule 1. Control active constraints (almost always)

- Active constraints may often be identified by engineering insight, but more generally requires optimization based on a detailed model.

  For example, consider the problem of minimizing the driving time between two cities (cost $J = T$). There is a single input ($u = $ fuel flow f [l/s]) and the optimal solution is often constrained. When driving a fast car, the active constraint may be the speed limit ($CV_1 = v$ [km/h] with setpoint v_{max}, e.g., $v_{max} = 100\,km/h$). When driving

Control Structure Selection, Table 2 Objectives of supervisory control layer

O1. Control primary "economic" variables CV_1 at setpoint using as degrees of freedom MV_1, which includes the setpoints to the regulatory layer ($y_{2s} = CV_{2s}$) as well as any "unused" degrees of freedom (u_1)

O2. Switch controlled variables (CV_1) depending on operating region, for example, because of change in active constraints

O3. Supervise the regulatory layer, for example, to avoid input saturation (u_2), which may destabilize the system

O4. Coordinate control loops (multivariable control) and reduce effect of interactions (decoupling)

O5. Provide feedforward action from measured disturbances

O6. Make use of additional inputs, for example, to improve the dynamic performance (usually combined with input midranging control) or to extend the steady-state operating range (split range control)

O7. Make use of extra measurements, for example, to estimate the primary variables CV_1

an old car, the active constraint maybe the maximum fuel flow ($CV_1 = f [l/s]$ with setpoint f_{max}). The latter corresponds to an input constraint ($u_{max} = f_{max}$) which is trivial to implement ("full gas"); the former corresponds to an output constraint ($y_{max} = v_{max}$) which requires a controller ("cruise control").

- For *"hard" output constraints*, which cannot be violated at any time, we need to introduce a *backoff* (safety margin) to guarantee feasibility. The backoff is defined as the difference between the optimal value and the actual setpoint, for example, we need to back off from the speed limit because of the possibility for measurement error and imperfect control

$$CV_{1,s} = CV_{1,max} - \text{backoff}$$

For example, to avoid exceeding the speed limit of 100 km/h, we may set backoff = 5 km/h, and use a setpoint $v_s = 95$ km/h rather than 100 km/h.

CV_1 Rule 2. For the remaining unconstrained degrees of freedom, look for "self-optimizing" variables which when held constant, indirectly lead to close-to-optimal operation, in spite of disturbances.

- Self-optimizing variables ($CV_1 = H_1 y$) are variables which when kept constant, indirectly (through the action of the feedback control system) lead to close-to optimal adjustment of the inputs (u) when there are disturbances (d).

- An ideal self-optimizing variable is the gradient of the cost function with respect to the unconstrained input. $CV_1 = dJ/du = J_u$
- More generally, since we rarely can measure the gradient J_u, we select $CV_1 = H_1 y$. The selection of a good H_1 is a nontrivial task, but some quantitative approaches are given below.

For example, consider again the problem of driving between two cities, but assume that the objective is to minimize the total fuel, $J = V$ [liters]., Here, driving at maximum speed will consume too much fuel, and driving too slow is also nonoptimal. This is an unconstrained optimization problem, and identifying a good CV_1 is not obvious. One option is to maintain a constant speed ($CV_1 = v$), but the optimal value of v may vary depending on the slope of the road. A more "self-optimizing" option, could be to keep a constant fuel rate ($CV_1 = f [l/s]$), which will imply that we drive slower uphill and faster downhill. More generally, one can control combinations, $CV_1 = H_1 y$ where H_1 is a "full" matrix.

CV_1 Rule 3. For the unconstrained degrees of freedom, one should *never* control a variable that reaches its maximum or minimum value at the optimum, for example, never try to control directly the cost J. Violation of this rule gives either infeasibility (if attempting to control J at a lower value than J_{min}) or nonuniqueness (if attempting to control J at higher value than J_{min}).

Assume again that we want to minimize the total fuel needed to drive between two cities, $J = V$ [l]. Then one should avoid fixing the

total fuel, $CV_1 = V$ [l], or, alternatively, avoid fixing the fuel consumption("gas mileage") in liters pr. km ($CV_1 = f$ [l/km]). Attempting to control the fuel consumption[l/km] <u>below</u> the car's minimum value is obviously not possible (infeasible). Alternatively, attempting to control the fuel consumption <u>above</u> its minimum value has two possible solutions; driving slower or faster than the optimum. Note that the policy of controlling the fuel rate f [l/s] at a fixed value will never become infeasible.

For CV_1-Rule 2, it is always possible to find good variable combinations (i.e., H_1 is a "full" matrix), at least locally, but whether or not it is possible to find good individual variables (H_1 is a selection matrix), is not obvious. To help identify potential "self-optimizing" variables ($CV_1 = c$) ,the following requirements may be used:

Requirement 1. The *optimal* value of c is insensitive to disturbances, that is, $dc_{opt}/dd = H_1F$ is small. Here $F = dy_{opt}/dd$ is the optimal sensitivity matrix (see below).

Requirement 2. The variable c is easy to measure and control accurately

Requirement 3. The value of c is sensitive to changes in the manipulated variable, u; that is, the gain, $G = HG^y$, from u to c is large (so that even a large error in controlled variable, c, results in only a small variation in u.) Equivalently, the optimum should be "flat" with respect to the variable, c. Here $G^y = dy/du$ is the measurement gain matrix (see below).

Requirement 4. For cases with two or more controlled variables c, the selected variables should not be closely correlated.

All four requirements should be satisfied. For example, for the operation of a marathon runner, the heart rate may be a good "self-optimizing" controlled variable c (to keep at constant setpoint). Let us check this against the four requirements. The optimal heart rate is weakly dependent on the disturbances (requirement 1) and the heart rate is easy to measure (requirement 2). The heart rate is quite sensitive to changes in power input (requirement 3). Requirement 4 does not apply since this is

a problem with only one unconstrained input (the power). In summary, the heart rate is a good candidate.

Regions and switching. If the optimal active constraints vary depending on the disturbances, new controlled variables (CV_1) must be identified (offline) for each active constraint region, and online switching is required to maintain optimality. In practise, it is easy to identify when to switch when one reaches a constraint. It is less obvious when to switch out of a constraint, but actually one simply has to monitor the value of the unconstrained CVs from the neighbouring regions and switch out of the constraint region when the unconstrained CV reaches its setpoint.

In general, one would like to simplify the control structure and reduce need for switching. This may require using a suboptimal CV_1 in some regions of active constraints. In this case, the setpoint for CV_1 may not be its nominally optimal value (which is the normal choice), but rather a "robust setpoint" (with backoff) which reduces the loss when we are outside the nominal constraint region.

Structure of supervisory layer. The supervisory layer may either be centralized, e.g., using model predictive control (MPC), or decomposed into simpler subcontrollers using standard elements, like decentralized control (PID), cascade control, selectors, decouplers, feedforward elements, ratio control, split range control, and input midrange control (also known as input resetting, valve position control or habituating control). In theory, the performance is better with the centralized approach (e.g., MPC), but the difference can be small when designed by a good engineer. The main reasons for using simpler elements is that (1) the system can be implemented in the existing "basic" control system, (2) it can be implemented with little model information, and (3) it can be build up gradually. However, such systems can quickly become complicated and difficult to understand for other than the engineer who designed it. Therefore, model-based centralized solutions (MPC) are often preferred because the design is more systematic and easier to modify.

Quantitative Approach for Selecting Economic Controlled Variables, CV_1

A quantitative approach for selecting economic controlled variables is to consider the effect of the choice $CV_1 = H_1y$ on the economic cost J when disturbances d occur. One should also include noise/errors (n^y) related to the measurements and inputs.

Step S1. *Define operational objectives (economic cost function J and constraints)*

We first quantify the operational objectives in terms of a scalar cost function J [\$/s] that should be minimized (or equivalently, a scalar profit function, $P = -J$, that should be maximized). For process control applications, this is usually easy, and typically we have

$$J = \text{cost feed} + \text{cost utilities (energy)}$$
$$- \text{value products [\$/s]}$$

Note that the economic cost function J is used to *select* the controlled variables (CV_1), and another cost function (J'), typically involving the deviation in CV_1 from their optimal setpoints CV_{1s}, is used for the actual controller design (e.g., using MPC).

Step S2. *Find optimal operation for expected disturbances*

Mathematically, the optimization problem can be formulated as

$$\min_u J(u, x, d)$$

subject to:

Model equations: $dx/dt = f(u, x, d)$
Operational constraints: $g(u, x, d) \leq 0$

In many cases, the economics are determined by the steady-state behavior, so we can set $dx/dt = 0$. The optimization problem should be resolved for the expected disturbances (d) to find the truly optimal operation policy, $u_{opt}(d)$. The nominal solution (d_{nom}) may be used to obtain the setpoints (CV_{1s}) for the selected controlled variables. In

practise, the optimum input $u_{opt}(d)$ cannot be realized, because of model error and unknown disturbances d, so we use a feeback implementation where u is adjusted to keep the selected variables CV_1 at their nominally optimal setpoints.

Together with obtaining the model, the optimization step S2 is often the most time consuming step in the entire plantwide control procedure.

Step S3. *Select supervisory (economic) controlled variables, CV_1*

CV_1-Rule 1: Control Active Constraints

A primary goal for solving the optimization problem is to find the expected regions of active constraints, and a constraint is said to be "active" if $g = 0$ at the optimum. The optimally active constraints will vary depending on disturbances (d) and market conditions (prices).

CV_1-Rule 2: Control Self-Optimizing Variables

After having identified (and controlled) the active constraints, one should consider the remaining lower-dimension unconstrained optimization problem, and for the remaining unconstrained degrees of freedom one should search for *control "self-optimizing" variables* c.

1. **"Brute force" approach.** Given a set of controlled variables $CV_1 = c = H_1y$, one computes the cost J(c,d) when we keep c constant ($c = c_s + H_1n^y$) for various disturbances (d) and measurement errors (n^y). In practise, this is done by running a large number of steady-state simulations to try to cover the expected future operation.

2. **"Local" approaches** based on a quadratic approximation of the cost J. Linear models are used for the effect of u and d on y.

$$y = G^yu + G_d^yd$$

This is discussed in more detail in Alstad et al. (2009) and references therein. The main local approaches are:

2A. **Maximum gain rule: maximize the minimum singular value of $G = H_1G^y$.**

In other words, the maximum gain rule, which essentially is a quantitative version of Requirements 1, 3 and 4 given above, says that one should control "sensitive" variables, with a large scaled gain G from the inputs (u) to $c = H_1 y$. This rule is good for pre-screening and also yields good insight.

2B. **Nullspace method.** This method yields optimal measurement combinations for the case with no noise, $n^y = 0$. One must first obtain the optimal measurement sensitivity matrix F, defined as

$$\mathbf{F} = dy^{opt}/dd.$$

Each column in **F** expresses the optimal change in the y's when the independent variable (u) is adjusted so that the system remains optimal with respect to the disturbance d. Usually, it is simplest to obtain F numerically by optimizing the model. Alternatively, we can obtain F from a quadratic approximation of the cost function

$$F = G_d^y - G^y J_{uu}^{-1} J_{ud}$$

Then, assuming that we have at least as many (independent) measurements y as the sum of the number of (independent) inputs (u) and disturbances (d), the optimal is to select $c = H_1 y$ such that

$$H_1 \mathbf{F} = 0$$

Note that H_1 is a nonsquare matrix, so $H_1 F = 0$ does not require that $H_1 = 0$ (which is a trivial uninteresting solution), but rather that H_1 is in the nullspace of F^T.

2C. **Exact local** method (loss method). This extends the nullspace method to include noise (n^y) and allows for any number of measurements. The noise and disturbances are normalized by introducing weighting matrices W_{ny} and W_d (which have the expected magnitudes along the diagonal) and then the expected loss, $L = J - J_{opt}(d)$, is minimized by selecting H_1 to solve the following problem

$$\min\_H_1 ||M(H_1)||_2$$

where 2 denotes the Frobenius norm and

$$M(H_1) = J_{uu}^{1/2}(H_1 G^y)^{-1} H_1 Y, Y$$
$$= [FW_d \ W_{ny}].$$

Note here that the optimal choice with $W_{ny} = 0$ (no noise) is to choose H_1 such that $H_1 F = 0$, which is the nullspace method. For the general case, when H_1 is a "full" matrix, this is a convex problem and the optimal solution is $H_1^T = (YY')^{-1} G^y Q$ where Q is any nonsingular matrix.

Regulatory Control Layer

The main purpose of the regulatory layer is to "stabilize" the plant, preferably using a *simple* control structure (e.g., single-loop PID controllers) which does not require changes during operation. "Stabilize" is here used in a more extended sense to mean that the process does not "drift" too far away from acceptable operation when there are disturbances. The regulatory layer should make it possible to use a "slow" supervisory control layer that does not require a detailed model of the high-frequency dynamics. Therefore, in addition to track the setpoints given by the supervisory layer (e.g., MPC), the regulatory layer may directly control primary variables (CV_1) that require fast and tight control, like economically important active constraints.

In general, the design of the regulatory layer involves the following structural decisions:

1. Selection of controlled outputs y_2 (among all candidate measurements y_m).
2. Selection of inputs $MV_2 = u_2$ (a subset of all available inputs u) to control the outputs y_2.
3. Pairing of inputs u_2 and outputs y_2 (since decentralized control is normally used).

Decisions 1 and 2 combined (IO selection) is equivalent to selecting H_2 (Fig. 3). Note that we do not "use up" any degrees of freedom in the regulatory layer because the set points (y_{2s})

become manipulated variables (MV_1) for the supervisory layer (see Fig. 3). Furthermore, since the set points are set by the supervisory layer in a cascade manner, the system eventually approaches the same steady-state (as defined by the choice of economic variables CV_1) regardless of the choice of controlled variables in the regulatory layer.

The inputs for the regulatory layer (u_2) are selected as a subset of all the available inputs (u). For stability reasons, one should avoid input saturation in the regulatory layer. In particular, one should avoid using inputs (in the set u_2) that are optimally constrained in some disturbance region. Otherwise, in order to avoid input saturation, one needs to include a backoff for the input when entering this operational region, and doing so will have an economic penalty.

In the regulatory layer, the outputs (y_2) are usually selected as individual measurements and they are often not important variables in themselves. Rather, they are "extra outputs" that are controlled in order to "stabilize" the system, and their setpoints (y_{2s}) are changed by the layer above, to obtain economical optimal operation. For example, in a distillation column one may control a temperature somewhere in the middle of the column ($y_2 = T$) in order to "stabilize" the column profile. Its setpoint ($y_{2s} = T_s$) is adjusted by the supervisory layer to obtain the desired product composition ($y_1 = c$).

Input-Output (IO) Selection for Regulatory Control (u_2, y_2)

Finding the truly optimal control structure, including selecting inputs and outputs for regulatory control, requires finding also the optimal controller parameters. This is an extremely difficult mathematical problem, at least if the controller K is decomposed into smaller controllers. In this section, we consider some approaches which does not require that the controller parameters be found. This is done by making assumptions related to achievable control performance (controllability) or perfect control.

Before we look at the approaches, note again that the IO-selection for regulatory control may be combined into a single decision, by considering the selection of

$$CV_2 = [y_2; u_1] = H_2 y$$

Here u_1 denotes the inputs that are <u>not</u> used by the regulatory control layer. This follows because we want to use all inputs u for control, so assuming that the set u is given, "selection of inputs u_2" (decision 2) is by elimination equivalent to "selection of inputs u_1." Note that CV_2 include all variables that we keep at desired (constant) values within the fast time horizon of the regulatory control layer, including the "unused" inputs u_1

Survey by Van de Wal and Jager

Van de Wal and Jager provide an overview of methods for input-output selection, some of which include:

1. "Accessibility" based on guaranteeing a cause–effect relationship between the selected inputs (u_2) and outputs (y_2). Use of such measures may eliminate unworkable control structures.
2. "State controllability and state observability" to ensure that any unstable modes can be stabilized using the selected inputs and outputs.
3. "Input-output controllability" analysis to ensure that y_2 can be acceptably controlled using u_2. This is based on scaling the system, and then analysing the transfer matrices $G_2(s)$ (from u_2 to y_2) and G_{d2} (from expected disturbances d to y_2). Some important controllability measures are right half plane zeros (unstable dynamics of the inverse), condition number, singular values, relative gain array, etc. One problem here is that there are many different measures, and it is not clear which should be given most emphasis.
4. "Achievable robust performance." This may be viewed as a more detailed version of input-output controllability, where several relevant issues are combined into a single measure. However, this requires that the control problem can actually be formulated clearly, which may be very difficult, as already mentioned.

In addition, it requires finding the optimal robust controller for the given problem, which may be very difficult.

Most of these methods are useful for analyzing a given structure (u_2, y_2) but less suitable for selection. Also, the list of methods is also incomplete, as disturbance rejection, which is probably the most important issue for the regulatory layer, is hardly considered.

A Systematic Approach for IO-Selection Based on Minimizing State Drift Caused by Disturbances

The objectives of the regulatory control layer are many, and Yelchuru and Skogestad (2013) list 13 partly conflicting objectives. To have a truly systematic approach to regulatory control design, including IO-selection, we would need to quantify all these partially conflicting objectives in terms of a scalar cost function J_2. We here consider a fairly general cost function,

$$J_2 = ||Wx||$$

which may be interpreted as the weighted state drift. One justification for considering the state drift, is that the regulatory layer should ensure that the system, as measured by the weighted states Wx, does not drift too far away from the desired state, and thus stays in the "linear region" when there are disturbances. Note that the cost J_2 is used to *select* controlled variables (CV_2) and not to design the controller (for which the cost may be the control error, $J_2' = ||CV_2 - CV_{2s}||$).

Within this framework, the IO-selection problem for the regulatory layer is then to select the nonsquare matrix H_2,

$$CV_2 = H_2y$$

where $y = [y_m; u]$, such that the cost J_2 is minimized. The cause for changes in J_2 are disturbances d, and we consider the linear model (in deviation variables)

$$y = G^y u + G_d^y d$$
$$x = G^x u + G_d^x d$$

where the G-matrices are transfer matrices. Here, G_d^x gives the effect of the disturbances on the states with no control, and the idea is to reduce the disturbance effect by closing the regulatory control loops. Within the "slow" time scale of the supervisory layer, we can assume that CV_2 is perfectly controlled and thus constant, or $CV_2 = 0$ in terms of deviation variables. This gives

$$CV_2 = H_2G^y u + H_2G_d^y d = 0$$

and solving with respect to u gives

$$u = - (H_2G^y)^{-1} (H_2G_d^y) d$$

and we have

$$x = P_d^x (H_2) d$$

where

$$P_d^x (H_2) = G_d^x - G^x (H_2G^y)^{-1} H_2G_d^y$$

is the disturbance effect for the "partially" controlled system with only the regulatory loops closed. Note that it is not generally possible to make $P_d^x = 0$ because we have more states than we have available inputs. To have a small "state drift," we want $J_2 = ||W P_d d||$ to be small, and to have a simple regulatory control system we want to close as few regulatory loops as possible. Assume that we have normalized the disturbances so that the norm of d is 1, then we can solve the following problem

For $0, 1, 2\ldots$ etc. loops closed solve: min_H_2||$M_2 (H_2)$ ||

where $M_2 = WP_d^x$ and $\dim (u2) = \dim (y2) =$ no. of loops closed.

By comparing the value of $||M_2 (H_2)||$ with different number of loops closed (i.e., with different H_2), we can then decide on an appropriate regulatory layer structure. For example, assume that we find that the value of J_2 is 110 (0 loops closed), 0.2 (1 loop), and 0.02 (2 loops), and assume we have scaled the disturbances and states such that a J_2-value less than about 1 is acceptable, then closing 1 regulatory loop is probably the best choice.

In principle, this is straightforward, but there are three remaining *issues*: (1) We need to choose an appropriate norm, (2) we should include measurement noise to avoid selecting insensitive measurements and (3) the problem must be solvable numerically.

Issue 1. The norm of M_2 should be evaluated in the frequency range between the "slow" bandwidth of the supervisory control layer (ω_{B1}) and the "fast" bandwidth of the regulatory control layer (ω_{B2}). However, since it is likely that the system sometimes operates without the supervisory layer, it is reasonable to evaluate the norm of P_d^x in the frequency range from 0 (steady state) to ω_{B2}. Since we want H_2 to be a constant (not frequency-dependent) matrix, it is reasonable to choose H_2 to minimize the norm of M_2 at the frequency where $||M_2||$ is expected to have its peak. For some mechanical systems, this may be at some resonance frequency, but for process control applications it is usually at steady state ($\omega = 0$), that is, we can use the steady-state gain matrices when computing P_d^x. In terms of the norm, we use the 2-norm (Frobenius norm), mainly because it has good numerical properties, and also because it has the interpretation of giving the expected variance in x for normally distributed disturbances.

Issues 2 and 3. If we include also measurement noise n^y, which we should, then the expected value of J_2 is minimized by solving the problem min_H_2 $||M_2(H_2)||_2$ where (Yelchuru and Skogestad 2013)

$$\mathbf{M}_2(\mathbf{H}_2) = \mathbf{J}_{2uu}^{1/2}(\mathbf{H}_2\mathbf{G}^y)^{-1}\mathbf{H}_2\mathbf{Y}_2$$

$$\mathbf{Y}_2 = [\mathbf{F}_2\mathbf{W}_d \quad \mathbf{W}_n]; \quad \mathbf{F}_2 = \frac{\partial \mathbf{y}_{opt}}{\partial \mathbf{d}}$$
$$= \mathbf{G}^y \mathbf{J}_{2uu}^{-1}\mathbf{J}_{2ud} - \mathbf{G}_{dy}$$

where $J_{2uu} \stackrel{\Delta}{=} \frac{\partial^2 J_2}{\partial u^2} = 2\mathbf{G}^{xT}\mathbf{W}^T\mathbf{W}\mathbf{G}^x$, $J_{2ud} \stackrel{\Delta}{=} \frac{\partial^2 J_2}{\partial u \partial d} = 2\mathbf{G}^{xT}\mathbf{W}^T\mathbf{W}\mathbf{G}_{dx}$,

Note that this is the same mathematical problem as the "exact local method" presented for selecting $CV_1 = H_1 y$ for minimizing the economic cost J, but because of the specific simple form

for the cost J_2, it is possible to obtain analytical formulas for the optimal sensitivity, F_2. Again, W_d and W_{ny} are diagonal matrices, expressing the expected magnitude of the disturbances (d) and noise (for y).

For the case when H_2 is a "full" matrix, this can be reformulated as a convex optimization problem and an explicit solution is

$$\mathbf{H}_2^T = (\mathbf{Y}_2\mathbf{Y}_2^T)^{-1}\mathbf{G}^y(\mathbf{G}^{yT}(\mathbf{Y}_2\mathbf{Y}_2^T)^{-1}\mathbf{G}^y)^{-1}\mathbf{J}_{2uu}^{1/2}$$

and from this we can find the optimal value of J_2. It may seem restrictive to assume that H_2 is a "full" matrix, because we usually want to control individual measurements, and then H_2 should be a selection matrix, with 1's and 0's. Fortunately, since we in this case want to control as many measurements (y_2) as inputs (u_2), we have that H_2 is square in the selected set, and the optimal value of J_2 when H_2 is a selection matrix is the same as when H_2 is a full matrix. The reason for this is that specifying (controlling) any linear combination of y_2, uniquely determines the individual y_2's, since dim(u_2) = dim(y_2). Thus, we can find the optimal selection matrix H_2, by searching through all the candidate square sets of y. This can be effectively solved using the branch and bound approach of Kariwala and Cao, or alternatively it can be solved as a mixed-integer problem with a quadratic program (QP) at each node (Yelchuru and Skogestad 2012). The approach of Yelchuru and Skogestad can also be applied to the case where we allow for disjunct sets of measurement combinations, which may give a lower J_2 in some cases.

Comments on the state drift approach.
1. We have assumed that we perfectly control y_2 using u_2, at least within the bandwidth of the regulatory control system. Once one has found a candidate control structure (H_2), one should check that it is possible to achieve acceptable control. This may be done by analyzing the input-output controllability of the system $y_2 = G_2u_2 + G_{2d}$ d, based on the transfer matrices $G_2 = H_2G^y$ and $G_{2d} = H_2G_d^y$. If the controllability of this system is not acceptable, then

one should consider the second-best matrix H_2 (with the second-best value of the state drift J_2) and so on.

2. The state drift cost drift $J_2 = ||Wx||$ is in principle independent of the economic cost (J). This is an advantage because we know that the economically optimal operation (e.g., active constraints) may change, whereas we would like the regulatory layer to remain unchanged. However, it is also a disadvantage, because the regulatory layer determines the initial response to disturbances, and we would like this initial response to be in the right direction economically, so that the required correction from the slower supervisory layer is as small as possible. Actually, this issue can be included by extending the state vector x to include also the economic controlled variables, CV_1, which is selected based on the economic cost J. The weight matrix W may then be used to adjust the relative weights of avoiding drift in the internal states x and economic controlled variables CV_1.

3. The above steady-state approach does not consider input-output pairing, for which dynamics are usually the main issue. The main pairing rule is to "pair close" in order to minimize the effective time delay between the selected input and output. For a more detailed approach, decentralized input-output controllability must be considered.

Summary and Future Directions

Control structure design involves the structural decisions that must be made before designing the actual controller, and it is in most cases a much more important step than the controller design. In spite of this, the theoretical tools for making the structural decisions are much less developed than for controller design. This chapter summarizes some approaches, and it is expected, or at least hoped, that this important area will further develop in the years to come.

The most important structural decision is usually related to selecting the economic controlled variables, $CV_1 = H_1y$, and the stabilizing controlled variables, $CV_2 = H_2y$. However, control engineers have traditionally not used the degrees of freedom in the matrices H_1 and H_2, and this chapter has summarized some approaches.

There has been a belief that the use of "advanced control," e.g., MPC, makes control structure design less important. However, this is not correct because also for MPC must one choose inputs ($MV_1 = CV_{2s}$) and outputs (CV_1). The selection of CV_1 may to some extent be avoided by use of "Dynamic Real-Time Optimization (DRTO)" or "Economic MPC," but these optimizing controllers usually operate on a slower time scale by sending setpoints to the basic control layer ($MV_1 = CV_{2s}$), which means that selecting the variables CV_2 is critical for achieving (close to) optimality on the fast time scale.

Controllability and Observability

H.L. Trentelman
Johann Bernoulli Institute for Mathematics and Computer Science, University of Groningen, Groningen, AV, The Netherlands

Abstract

State controllability and observability are key properties in linear input–output systems in state-space form. In the state-space approach, the relation between inputs and outputs is represented using the state variables of the system. A natural question is then to what extent it is possible to manipulate the values of the state vector by means of an appropriate choice of the input function. The concepts of controllability, reachability, and null controllability address this issue. Another important question is whether it is possible to uniquely determine the values of the state vector from knowledge of the input and output

signals over a given time interval. This question is dealt with using the concept of observability.

Keywords

Introduction

In the state-space approach to input–output systems, the relation between input signals and output signals is represented by means of two equations. In the continuous-time case, the first of these equations is a first-order vector differential equation driven by the input signal and is often called *the state equation*. The second equation is an algebraic equation, often called the *output equation*. The unknown in the differential equation is called the *state vector* of the system. Given a particular input signal and initial value of the state vector, the state equation generates a unique solution, called the state trajectory of the system. The output equation determines the corresponding output signal as a function of this state trajectory and the input signal. Thus, in the state space approach, the input–output behavior of the system is obtained using the state vector as an intermediate variable.

In the context of input–output systems in state-space form, the properties of controllability and observability characterize the interaction between the input, the state, and the output. In particular, controllability describes the ability to manipulate the state vector of the system by applying appropriate input signals. Observability describes the ability to determine the values of the state vector from knowledge of the input and output over a certain time interval. The properties of controllability and observability are fundamental properties that play a major role in the analysis and control of linear input–output systems in state-space form.

Systems with Inputs and Outputs

Consider a continuous-time, linear, time-invariant, input–output system in state-space form represented by the equations

$$\dot{x}(t) = Ax(t) + Bu(t),$$
$$y(t) = Cx(t) + Du(t). \qquad (1)$$

This system is referred to as Σ. In Eq. (1), A, B, C, and D are maps (or matrices), and the functions x, u, and y are considered to be defined on the real axis $\mathbb{R}$ or on any subinterval of it. In particular, one often assumes the domain of definition to be the nonnegative part of $\mathbb{R}$, which is without loss of generality since the system is time-invariant. The function u is called the *input*, and its values are assumed to be given. The class of admissible input functions is denoted by **U**. Often, **U** is the class of piecewise continuous or locally integrable functions, but for most purposes, the exact class from which the input functions are chosen is not important. We assume that input functions take values in an m-dimensional space $\mathcal{U}$, which we often identify with $\mathbb{R}^m$. The first equation of Σ is an ordinary differential equation for the variable x. For a given initial value of x and input function u, the function x is completely determined by this equation. The variable x is called the *state variable* and it is assumed to take values in an n-dimensional space $\mathcal{X}$. The space $\mathcal{X}$ is called the *state space*. It is usually identified with $\mathbb{R}^n$. Finally, y is called the *output* of the system and takes values in a p-dimensional space $\mathcal{Y}$, which we identify with $\mathbb{R}^p$. Since the system Σ is completely determined by the maps (or matrices) A, B, C, and D, we identify Σ with the quadruple (A, B, C, D).

The solution of the differential equation of Σ with initial value $x(0) = x_0$ is denoted as $x_u(t, x_0)$. It can be given explicitly using the variation-of-constants formula, namely,

$$x_u(t, x_0) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)\,\mathrm{d}\tau. \quad (2)$$

The corresponding value of y is denoted by $y_u(t, x_0)$. As a consequence of (2), we have

$$y_u(t, x_0) = Ce^{At}x_0 + \int_0^t K(t - \tau)u(\tau)\,\mathrm{d}\tau$$
$$+ Du(t), \qquad (3)$$

where $K(t) := Ce^{At}B$. In the case $D = 0$, it is customary to call $K(t)$ the *impulse response*. In the general case, one would call the distribution $K(t) + D\delta(t)$ the impulse response.

Controllability

Controllability is concerned with the ability to manipulate the state by choosing an appropriate input signal, thus steering the current state to a desired future state in a given finite time. Thus, in particular, in the differential equation in (1), we study the relation between u and x. We investigate to what extent one can influence the state x by a suitable choice of the input u.

For this purpose, we introduce the (at time T) *reachable space* $\mathcal{W}_T$, defined as the space of points x_1 for which there exists an input u such that $x_u(T, 0) = x_1$, i.e., the set of points that can be reached from the origin at time T. It follows from the linearity of the differential equation that $\mathcal{W}_T$ is a linear subspace of $\mathcal{X}$. In fact, (2) implies

$$\mathcal{W}_T = \left\{ \int_0^T e^{A(T-\tau)}Bu(\tau)\mathrm{d}\tau \,\middle|\, u \in \mathbf{U} \right\}. \quad (4)$$

We call system Σ *reachable at time T* if every point can be reached from the origin, i.e., if $\mathcal{W}_T = \mathcal{X}$. It follows from (2) that if the system is reachable at time T, every point can be reached from every point at time T, because the condition for the point x_1 to be reachable from x_0 at time T is

$$x_1 - e^{AT}x_0 \in \mathcal{W}_T.$$

The property that every point is reachable from any point in a given time interval [0, T] is called *controllability (at T)*. Finally, we have the concept of *null controllability*, i.e., the possibility to reach the origin from an arbitrary initial point. According to (2), for a point x_0 to be null controllable at T, we must have

$$e^{AT} x_0 + \int_0^T e^{A(T-\tau)} B u(\tau)\, \mathrm{d}\tau = 0$$

for some $u \in \mathbf{U}$. We observe that x_0 is null controllable at T (by the control u) if and only if $-e^{AT} x_0$ is reachable at T (by the control u). Since e^{AT} is invertible, we see that Σ is null controllable at T if and only if Σ is reachable at T. Henceforth, we refer to the equivalent properties reachability, controllability, null controllability simply as controllability (at T). It should be remarked that the equivalence of these concepts does not hold in other situations, e.g., for discrete-time systems. We intend to obtain an explicit expression for the space $\mathcal{W}_T$ and, based on this, an explicit condition for controllability. This is provided by the following result.

Theorem 1 *Let η be an n-dimensional row vector and $T > 0$. Then the following statements are equivalent:*
1. *$\eta \perp \mathcal{W}_T$ (i.e., $\eta x = 0$ for all $x \in \mathcal{W}_T$).*
2. *$\eta e^{tA} B = 0$ for $0 \le t \le T$.*
3. *$\eta A^k B = 0$ for $k = 0, 1, 2, \ldots$.*
4. *$\eta (B\ AB\ \cdots\ A^{n-1} B) = 0$.*

Proof (i) $\Leftrightarrow$ (ii) If $\eta \perp \mathcal{W}_T$, then by Eq. (4):

$$\int_0^T \eta e^{A(T-\tau)} B u(\tau)\, \mathrm{d}\tau = 0 \qquad (5)$$

for every $u \in \mathbf{U}$. Choosing $u(t) = B^{\mathrm{T}} e^{A^{\mathrm{T}}(T-t)} \eta^{\mathrm{T}}$ for $0 \le t \le T$ yields

$$\int_0^T \left\| \eta e^{A(T-\tau)} B \right\|^2 \mathrm{d}\tau = 0,$$

from which (ii) follows. Conversely, assume that (ii) holds. Then (5) holds and hence (i) follows.

(ii) $\Leftrightarrow$ (iii) This is obtained by power series expansion of e^{At} $\left(= \sum_{k=0}^{\infty} \frac{t^k}{k!} A^k\right)$.

(iii) $\Leftrightarrow$ (iv) This follows immediately from the evaluation of the vector-matrix product.

(iv) $\Leftrightarrow$ (iii) This implication is based on the Cayley-Hamilton Theorem. According to this theorem, A^n is a linear combination of $I, A, \ldots, A^{n-1}$. By induction, it follows

that A^k $(k > n)$ is a linear combination of $I, A, \ldots, A^{n-1}$ as well. Therefore, $\eta A^k B = 0$ for $k = 0, 1, \ldots, n - 1$ implies that $\eta A^k B = 0$ for all $k \in \mathbb{N}$. $\square$

As an immediate consequence of the previous theorem, we find that at time T reachable subspace $\mathcal{W}_T$ can be expressed in terms of the maps A and B as follows.

Corollary 1

$$\mathcal{W}_T = \mathrm{im}\,(B\ \ AB\ \ \cdots\ \ A^{n-1} B).$$

This implies that, in fact, $\mathcal{W}_T$ is independent of T, for $T > 0$. Because of this, we often use $\mathcal{W}$ instead of $\mathcal{W}_T$ and call this subspace the reachable subspace of Σ. This subspace of the state space has the following geometric characterization in terms of the maps A and B.

Corollary 2 *$\mathcal{W}$ is the smallest A-invariant subspace containing $\mathcal{B} := \mathrm{im}\,B$. Explicitly, $\mathcal{W}$ is A-invariant, $\mathcal{B} \subset \mathcal{W}$, and any A-invariant subspace $\mathcal{L}$ satisfying $\mathcal{B} \subset \mathcal{L}$ also satisfies $\mathcal{W} \subset \mathcal{L}$. We denote the smallest A-invariant subspace containing $\mathcal{B}$ by $\langle A | \mathcal{B} \rangle$, so that we can write $\mathcal{W} = \langle A | \mathcal{B} \rangle$. For the space $\langle A | \mathcal{B} \rangle$, we have the following explicit formula*
$$\langle A | \mathcal{B} \rangle = \mathcal{B} + A\mathcal{B} + \cdots + A^{n-1}\mathcal{B}.$$

Corollary 3 *The following statements are equivalent.*
1. *There exists $T > 0$ such that system Σ is controllable at T.*
2. *$\langle A | \mathcal{B} \rangle = \mathcal{X}$.*
3. *Rank $(B\ AB \cdots A^{n-1} B) = n$.*
4. *The system Σ is controllable at T for all $T > 0$.*

We say that the matrix pair (A, B) is *controllable* if one of these equivalent conditions is satisfied.

Example 1 Let A and B be defined by

$$A := \begin{pmatrix} -2 & -6 \\ 2 & 5 \end{pmatrix}, \qquad B := \begin{pmatrix} -3 \\ 2 \end{pmatrix}.$$

Then $(B\ AB) = \begin{pmatrix} -3 & -6 \\ 2 & 4 \end{pmatrix}$, $\mathrm{rank}(B\ AB) = 1$, and consequently, (A, B) is not controllable. The reachable subspace is the span of $(B\ AB)$, i.e., the

line given by the equation $2x_1 + 3x_2 = 0$. This can also be seen as follows. Let $z := 2x_1 + 3x_2$, then $\dot{z} = z$. Hence, if $z(0) = 0$, which is the case if $x(0) = 0$, we must have $z(t) = 0$ for all $t \geq 0$.

Observability

In this section, we include the second of equations (1), $y = Cx + Du$, in our considerations. Specifically, we investigate to what extent it is possible to reconstruct the state x if the input u and the output y are known. The motivation is that we often can measure the output and prescribe (and hence know) the input, whereas the state variable is *hidden*.

Definition 2 Two states x_0 and x_1 in $\mathcal{X}$ are called *indistinguishable* on the interval $[0, T]$ if for any input u we have $y_u(t, x_0) = y_u(t, x_1)$, for all $0 \leq t \leq T$.

Hence, x_0 and x_1 are indistinguishable if they give rise to the same output values for every input u. According to (3), for x_0 and x_1 to be indistinguishable on $[0, T]$, we must have that

$$
Ce^{At}x_0 + \int_0^t K(t - \tau) u(\tau) \, d\tau + Du(t)
$$
$$
= Ce^{At}x_1 + \int_0^t K(t - \tau) u(\tau) \, d\tau + Du(t)
$$

for $0 \leq t \leq T$ and for any input signal u. We note that the input signal does not affect distinguishability, i.e., if one u is able to distinguish between two states, then any input is. In fact, x_0 and x_1 are indistinguishable if and only if $Ce^{At}x_0 = Ce^{At}x_1$ ($0 \leq t \leq T$). Obviously, x_0 and x_1 are indistinguishable if and only if $v := x_0 - x_1$ and 0 are indistinguishable. By applying Theorem 1 with $\eta = v^T$ nonzero and transposing the equations, it follows that $Ce^{At}x_0 = Ce^{At}x_1$ ($0 \leq t \leq T$) if and only if $Ce^{At}v = 0$ ($0 \leq t \leq T$) and hence if and only if $CA^k v = 0$ ($k = 0, 1, 2, \ldots$). The Cayley-Hamilton Theorem implies that we need to consider the first n terms only, i.e.,

$$
\begin{pmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{pmatrix} v = 0. \tag{6}
$$

As a consequence, the distinguishability of two vectors does not depend on T. The space of vectors v for which (6) holds is denoted $\langle \ker C \,|\, A \rangle$ and called the *unobservable subspace*. It is equivalently characterized as the intersection of the spaces $\ker CA^k$ for $k = 0, \ldots, n-1$, i.e.,

$$
\langle \ker C \,|\, A \rangle = \bigcap_{k=0}^{n-1} \ker CA^k.
$$

Equivalently, $\langle \ker C \,|\, A \rangle$ is the largest A-invariant subspace contained in $\ker C$. Finally, another characterization is "$v \in \langle \ker C \,|\, A \rangle$ if and only if $y_0(t, v)$ is identically zero," where the subscript "0" refers to the zero input.

Definition 3 System Σ is called *observable* if any two distinct states are not indistinguishable.

The previous considerations immediately lead to the result.

Theorem 2 *The following statements are equivalent.*
1. *The system Σ is observable.*
2. *Every nonzero state is not indistinguishable from the origin.*
3. $\langle ker\, C \,|\, A \rangle = 0$.
4. $Ce^{At}v = 0$ ($0 \leq t \leq T$) $\Rightarrow v = 0$.
5. *Rank* $\begin{pmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{pmatrix} = n$.

Since observability is completely determined by the matrix pair (C, A), we will say "(C, A) is observable" instead of "system Σ is observable."

There is a remarkable relation between the controllability and observability properties, which is referred to as *duality*. This property is most conspicuous from the conditions (3) in Corollary 3 and (5) in Theorem 2, respectively.

Specifically, (C, A) is observable if and only if (A^T, C^T) is controllable. As a consequence of duality, many theorems on controllability can be translated into theorems on observability and vice versa by mere transposition of matrices.

Example 2 Let

$$A := \begin{pmatrix} -11 & 3 \\ -3 & -5 \end{pmatrix}, \quad B := \begin{pmatrix} 1 \\ 1 \end{pmatrix},$$
$$C := (1 \quad -1),$$

Then

$$\mathrm{rank} \begin{pmatrix} C \\ CA \end{pmatrix} = \mathrm{rank} \begin{pmatrix} 1 & -1 \\ -8 & 8 \end{pmatrix} = 1,$$

hence, (C, A) is not observable. Notice that if $v \in \langle \ker C \mid A \rangle$ and $u = 0$, identically, then $y = 0$, identically. In this example, $\langle \ker C \mid A \rangle$ is the span of $(1, 1)^T$.

Summary and Future Directions

The property of controllability can be tested by means of a rank test on a matrix involving the maps A and B appearing in the state equation of the system. Alternatively, controllability is equivalent to the property that the reachable subspace of the system is equal to the state space. The property of observability allows a rank test on a matrix involving the maps A and C appearing in the system equations. An alternative characterization of this property is that the unobservable subspace of the system is equal to the zero subspace. Concepts of controllability and observability have also been defined for discrete-time systems and, more generally, for time-varying systems and for continuous-time and discrete-time nonlinear systems.

Controller Performance Monitoring

Sirish L. Shah
Department of Chemical and Materials
Engineering, University of Alberta Edmonton,
Edmonton, AB, Canada

Abstract

Process control performance is a cornerstone of operational excellence in a broad spectrum of industries such as refining, petrochemicals, pulp and paper, mineral processing, power and waste water treatment. Control performance assessment and monitoring applications have become mainstream in these industries and are changing the maintenance methodology surrounding control assets from predictive to condition based. The large numbers of these assets on most sites compared to the number of maintenance and control personnel have made monitoring and diagnosing control problems challenging. For this reason, automated controller performance monitoring technologies have been readily embraced by these industries.

This entry discusses the theory as well as practical application of controller performance monitoring tools as a requisite for monitoring and maintaining basic as well as advanced process control (APC) assets in the process industry. The section begins with the introduction to the theory of performance assessment as a technique for assessing the performance of the basic control loops in a plant. Performance assessment allows detection of performance degradation in the basic control loops in a plant by monitoring the variance in the process variable and comparing it to that of a minimum variance controller. Other metrics of controller performance are also reviewed. The resulting indices of performance give an indication of the level of performance of the controller and an indication of the action required to improve its performance; the diagnosis of poor performance may lead one to look at remediation alternatives such as: retuning controller parameters or process reengineering to reduce delays or implementation of feed-forward control or attribute poor performance to faulty actuators or other process nonlinearities.

Keywords

Time series analysis; Minimum variance control; Control loop performance assessment; Performance monitoring; Fault detection and diagnosis

Introduction

A typical industrial process, as in a petroleum refinery or a petrochemical complex, includes thousands of control loops. Instrumentation technicians and engineers maintain and service these loops, but rather infrequently. However, industrial studies have shown that as many as 60 % of control loops may have poor tuning or configuration or actuator problems and may therefore be responsible for suboptimal process performance. As a result, monitoring of such control strategies to detect and diagnose cause(s) of unsatisfactory performance has received increasing attention from industrial engineers. Specifically the methodology of data-based controller performance monitoring (CPM) is able to answer questions such as the following: Is the controller doing its job satisfactorily and if not, what is the cause of poor performance?

The performance of process control assets is monitored on a daily basis and compared with industry benchmarks. The monitoring system also provides diagnostic guidance for poorly performing control assets. Many industrial sites have

established reporting and remediation workflows to ensure that improvement activities are carried out in an expedient manner. Plant-wide performance metrics can provide insight into company-wide process control performance. Closed-loop tuning and modeling tools can also be deployed to aid with the improvement activities. Survey articles by Thornhill and Horch (2007) and Shardt et al. (2012) provide a good overview of the overall state of CPM and the related diagnosis issues. CPM software is now readily available from most DCS vendors and has already been implemented successfully at many large-scale industrial sites throughout the world.

Univariate Control Loop Performance Assessment with Minimum Variance Control as Benchmark

It has been shown by Harris (1989) that for a system with time delay d, a portion of the output variance is feedback control invariant and can be estimated from routine operating data. This is the so-called minimum variance output. Consider the closed-loop system shown in Fig. 1, where Q is the controller transfer function, $\tilde{T}$ is the process transfer function, d is the process delay (in terms of sample periods), and N is the disturbance transfer function driven by random white-noise sequence, a_t.

In the regulatory mode (when the set point is constant), the closed-loop transfer function relating the process output and the disturbance is given by

Closed-loop response: $y_t = \left(\dfrac{N}{1 + q^{-d}\tilde{T}Q} \right) a_t$
Controller Performance Monitoring, Fig. 1 Block diagram of a regulatory control loop

Note that all transfer functions are expressed for the discrete time case in terms of the backshift operator, q^{-1}. N represents the disturbance transfer function with numerator and denominator polynomials in q^{-1}. The division of the numerator by the denominator can be rewritten as: $N = F + q^{-d}R$, where the quotient term, $F = F_0 + F_1 q^{-1} + \cdots + F_{d-1} q^{-(d-1)}$ is a polynomial of order $(d-1)$ and the remainder, R is a transfer function. The closed-loop transfer function can be reexpressed, after algebraic manipulation as

$$y_t = \left(\frac{N}{1 + q^{-d}\tilde{T}Q} \right) a_t$$

$$= \left(\frac{F + q^{-d}R}{1 + q^{-d}\tilde{T}Q} \right) a_t$$

$$= \left(\frac{F\left(1 + q^{-d}\tilde{T}Q\right) + q^{-d}\left(R - F\tilde{T}Q\right)}{1 + q^{-d}\tilde{T}Q} \right) a_t$$

$$= \left(F + q^{-d}\frac{R - F\tilde{T}Q}{1 + q^{-d}\tilde{T}Q} \right) a_t$$

$$= \underbrace{F_0 a_t + F_1 a_{t-1} + \cdots + F_{d-1} a_{t-d+1}}_{e_t}$$

$$+ \underbrace{L_0 a_{t-d} + L_1 a_{t-d-1} + \cdots}_{w_{t-d}}$$

The closed-loop output can then be expressed as

$$y_t = e_t + w_{t-d}$$

where $e_t = F a_t$ corresponds to the first $d - 1$ lags of the closed-loop expression for the output, y_t, and more importantly is independent of the controller, Q, or it is controller invariant, while w_{t-d} is dependent on the controller. The variance of the output is then given by

$$Var(y_t) = Var(e_t) + Var(w_{t-d}) \geq Var(e_t)$$

Since e_t is controller invariant, it provides the lower bound on the output variance. This is naturally achieved if $w_{t-d} = 0$, that is, when $R = F\tilde{T}Q$ or when the controller is a minimum variance controller with $Q = \frac{R}{F\tilde{T}}$. If the total output variance is denoted as $Var(y_t) = \sigma^2$, then

the lowest achievable variance is $Var(e_t) = \sigma_{mv}^2$. To obtain an estimate of the lowest achievable variance from the time series of the process output, one needs to model the closed-loop output data y_t by a moving average process such as

$$y_t = \underbrace{f_0 a_t + f_1 a_{t-1} + \cdots + f_{d-1} a_{t-(d-1)}}_{e_t}$$
$$+ f_d a_{t-d} + f_{d+1} a_{t-(d+1)} + \cdots \quad (1)$$

The controller-invariant term e_t can then be estimated by time series analysis of routine closed-loop operating data and subsequently used as a benchmark measure of theoretically achievable absolute lower bound of output variance to assess control loop performance. Harris (1989),

Desborough and Harris (1992), and Huang and Shah (1999) have derived algorithms for the calculation of this minimum variance term.

Multiplying Eq. (1) by $a_t, a_{t-1}, \ldots, a_{t-d+1}$, respectively, and then taking the expectation of both sides of the equation yield the sample covariance terms:

$$\left. \begin{array}{c} r_{ya}(0) = E[y_t a_t] = f_0 \sigma_a^2 \\ r_{ya}(1) = E[y_t a_{t-1}] = f_1 \sigma_a^2 \\ r_{ya}(2) = E[y_t a_{t-2}] = f_2 \sigma_a^2 \\ \vdots \\ r_{ya}(d-1) = E[y_t a_{t-d+1}] = f_{d-1} \sigma_a^2 \end{array} \right\} \quad (2)$$

The minimum variance or the invariant portion of output variance is

$$\left. \begin{array}{l} \sigma_{mv}^2 = \left(f_0^2 + f_1^2 + f_2^2 + \cdots + f_{d-1}^2 \right) \sigma_a^2 \\ \\ = \left[\left(\dfrac{r_{ya}(0)}{\sigma_a^2} \right)^2 + \left(\dfrac{r_{ya}(1)}{\sigma_a^2} \right)^2 + \left(\dfrac{r_{ya}(2)}{\sigma_a^2} \right)^2 + \left(\dfrac{r_{ya}(d-1)}{\sigma_a^2} \right)^2 \right] \sigma_a^2 \\ \\ = \left[r_{ya}^2(0) + r_{ya}^2(1) + r_{ya}^2(2) + \cdots + r_{ya}^2(d-1) \right] / \sigma_a^2 \end{array} \right\} \quad (3)$$

A measure of controller performance index can then be defined as

$$\eta(d) = \sigma_{mv}^2 / \sigma_y^2 \quad (4)$$

Substituting Eq. (3) into Eq. (4) yields

$$\eta(d) = \left[r_{ya}^2(0) + r_{ya}^2(1) + r_{ya}^2(2) + \cdots + r_{ya}^2(d-1) \right] / \sigma_y^2 \sigma_a^2$$
$$= \rho_{ya}^2(0) + \rho_{ya}^2(1) + \rho_{ya}^2(2) + \cdots + \rho_{ya}^2(d-1)$$
$$= ZZ^T$$

where Z is the vector of cross correlation coefficients between y_t and a_t for lags 0 to $d-1$ and is denoted as

$$Z = \left[\rho_{ya}(0) \, \rho_{ya}(1) \, \rho_{ya}(2) \ldots \rho_{ya}(d-1) \right]$$

Although a_t is unknown, it can be replaced by the estimated innovation sequence $\hat{a}_t$. The estimate $\hat{a}_t$ is obtained by whitening the process output variable y_t via time series analysis. This algorithm is denoted as the FCOR algorithm

for Filtering and CORrelation analysis (Huang and Shah 1999). This derivation assumes that the delay, d, be known a priori. In practice, however, a priori knowledge of time delays may not always be available. It is therefore useful to assume a range of time delays and then calculate performance indices over this range of the time delays. The indices over a range of time delays are also known as extended horizon performance indices (Thornhill et al. 1999). Through pattern recognition, one can tell the performance of the loop by visualizing the patterns of the performance indices versus time delays. There is a clear relation between performance indices curve and the impulse response curve of the control loop.

Consider a simple case where the process is subject to random disturbances. Figure 2 is one example of performance evaluation for a control loop in the presence of disturbances. This figure shows time-series of process variable data for both loops in the left column, closed-loop impulse responses (middle column) and corresponding performance indices (labeled as PI on the right column). From the impulse responses, one can see that the loop under the first set of tuning constants (denoted as TAG1.PV) has better performance; the loop under the second set of tuning constants (denoted as TAG5.PV) has oscillatory behavior, indicating a relatively poor control performance. With performance index "1" indicating the best possible performance and index "0" indicating the worst performance, performance indices for the first controller tuning (shown on the upper-right plot) approach "1" within 4 time lags, while performance indices for the second controller tuning (shown on the bottom-right plot) take 10 time lags to approach "0.7." In addition, performance indices for the second tuning show ripples as they approach an asymptotic limit, indicating a possible oscillation in the loop.

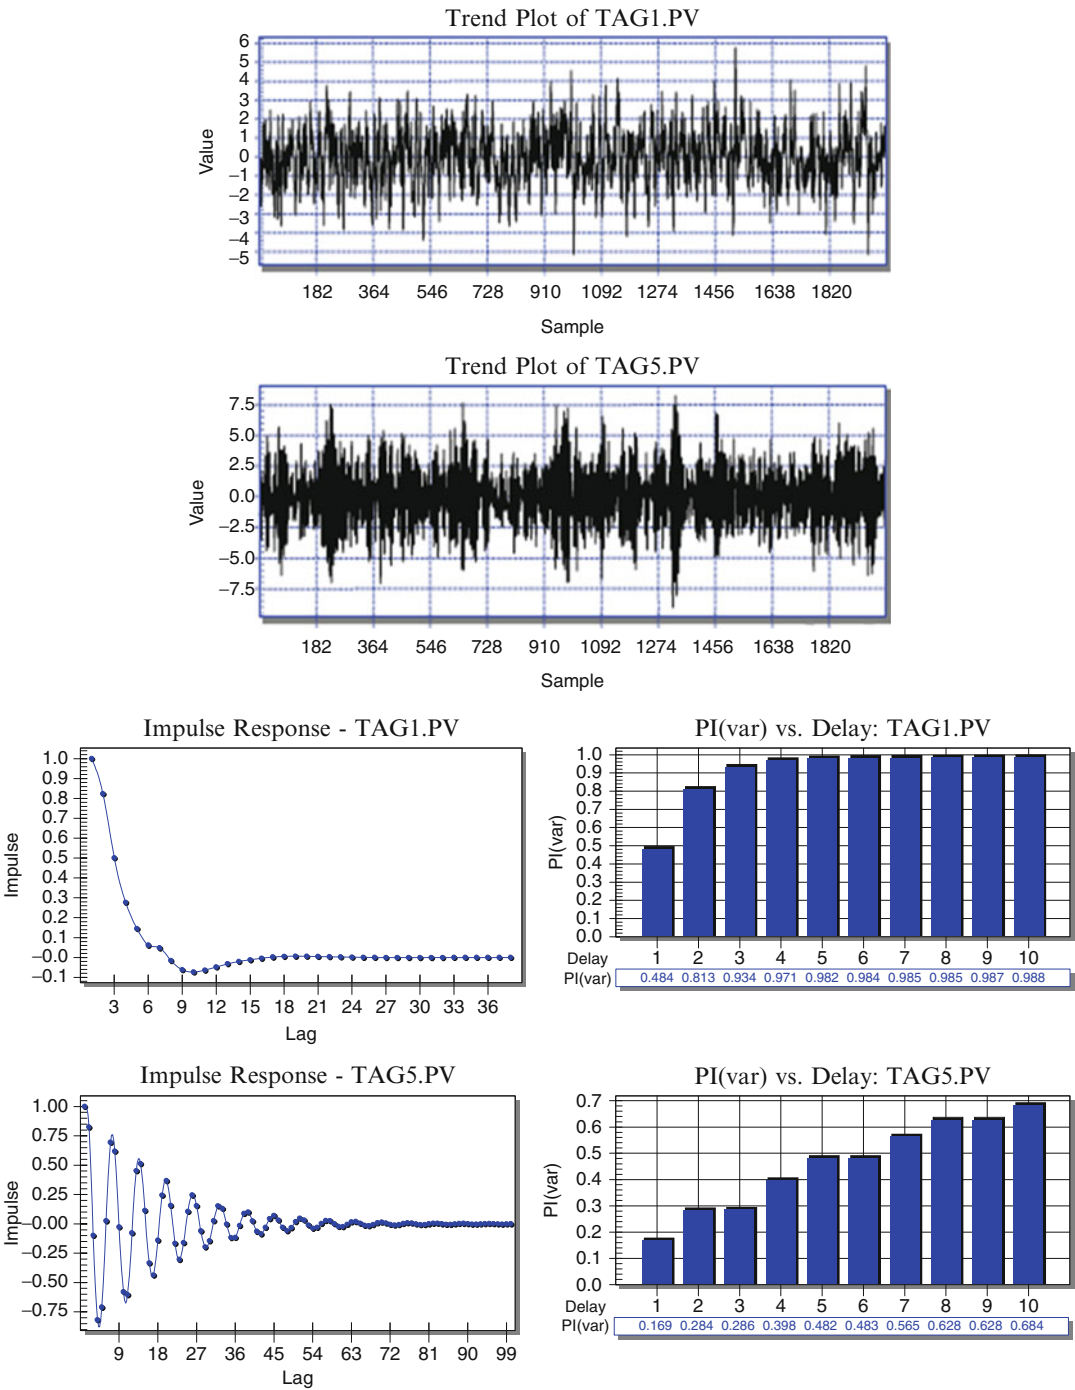
Notice that one cannot rank performance of these two controller settings from the noisy time-series data. Instead, we can calculate performance indices over a range of time delays (from 1 to 10). The result is shown on the right column plots of Fig. 2. These simulations correspond to the same process with different controller tuning constants.

It is clear from these plots that performance indices trajectory depends on dynamics of the disturbance and controller tuning.

It is important to note that the minimum variance is just one of several benchmarks for obtaining a controller performance metric. It is seldom practical to implement minimum variance control as it typically will require aggressive actuator action. However, the minimum variance benchmark serves to provide an indication of the opportunity in improving control performance; that is, should the performance index $\eta(d)$ be near or just above zero, then it gives the user an idea of the benefits possible in improving the control performance of that loop.

Performance Assessment and Diagnosis of Univariate Control Loop Using Alternative Performance Indicators

In addition to the performance index for performance assessment, there are several alternative indicators of control loop performance. These are discussed next.

Autocorrelation function: The autocorrelation function (ACF) of the output error, shown in Fig. 3, is an approximate measure of how close the existing controller is to minimum variance condition or how predictable the error is over the time horizon of interest. If the controller is under minimum variance condition then the autocorrelation function should decay to zero after "$d - 1$" lags where "d" is the delay of the process. In other words, there should be no predictable information beyond time lag $d - 1$. The rate at which the autocorrelation decays to zero after "$d - 1$" lags indicates how close the existing controller is to the minimum variance condition. Since it is straightforward to calculate autocorrelation using process data, the autocorrelation function is often used as a first-pass test before carrying out further performance analysis.
Impulse response: An impulse response function curve represents the closed-loop impulse


Controller Performance Monitoring, Fig. 2 Time series of process variable (top), corresponding impulse responses (left column) and their performance indices (right column).
Controller Performance Monitoring, Fig. 3
Autocorrelation function of the controller error

Controller Performance Monitoring, Fig. 4
Impulse responses estimated from routine operating data

response between the whitened disturbance sequence and the process output. This function is a direct measure of how well the controller is performing in rejecting disturbances or tracking set-point changes. Under stochastic framework, this impulse response function may be calculated using time series model such as an Autoregressive Moving Average (ARMA) or Autoregressive with Integrated Moving Average (ARIMA) model. Once an ARMA type of time series model is estimated, the infinite-order moving average representation of the model shown in Eq. (1) can be obtained through a long division of the ARMA model. As shown in Huang and Shah (1999), the coefficients of the moving average model, Eq. (1), are the closed-loop impulse response coefficients of the process between whitened disturbances and the process output. Figure 4 shows closed-loop impulse responses of a control loop with two different control tunings. Clearly they denote two different closed-loop dynamic responses: one is slow and smooth, and the other one is relatively fast and slightly oscillatory. The sum of square of the impulse response coefficients is the variance of the data.

Spectral analysis: The closed-loop frequency response of the process is an alternative way to assess control loop performance. Spectral analysis of output data easily allows one to detect oscillations, offsets, and measurement noise present in the process. The closed-loop frequency response is often plotted together with the closed-loop frequency response under minimum variance control. This is to check the possibility of performance improvement through controller tunings. The comparison gives a measure of how close the existing controller is to the minimum variance condition. In addition, it also provides the frequency range in which the controller significantly deviates from minimum variance condition. Large deviation in the low-frequency range typically indicates lack of integral action or weak proportional gain. Large peaks in the medium-frequency range typically indicate an overtuned controller or presence of oscillatory disturbances. Large deviation in the high-frequency range typically indicates significant measurement noise. As an illustrative example, frequency responses of two control loops are shown in Fig. 5. The left graph of the figure shows that closed-loop

Closed-Loop vs. Min. Variance Output Response
TAG1.PV

Closed-Loop vs. Min. Variance Output Response
TAG5.PV

Controller Performance Monitoring, Fig. 5   Frequency response estimated from routine operating data

frequency response of the existing controller is almost the same as the frequency response under minimum variance control. A peak at the mid-frequency indicates possible overtuned control. The right graph of Fig. 5 shows that the frequency response of the existing controller is oscillatory, indicating a possible overtuned controller or the presence of an oscillatory disturbance at the peak frequency; otherwise the controller is close to minimum variance condition.

Segmentation of performance indices: Most process data exhibit time- varying dynamics; i.e., the process transfer function or the disturbance transfer function is time variant. Performance assessment with a non-overlapping sliding data window that can track time-varying dynamics

is therefore often desirable. For example, segmentation of data may lead to some insight into any cyclical behavior of the process variation in controller performance during, e.g., day/night or due to shift change. Figure 6 is an example of performance segmentation over a 200 data point window.

Performance Assessment of Univariate Control Loops Using User-Specified Benchmarks

The increasing level of global competitiveness has pushed chemical plants into high-performance operating regions that require advanced process control technology. See the

articles ► Control Hierarchy of Large Processing Plants: An Overview and ► Control Structure Selection. Consequently, the industry has an increasing need to upgrade the conventional PID controllers to advanced control systems. The most natural questions to ask for such an upgrading are as follows. Has the advanced controller improved performance as expected? If yes, where is the improvement and can it be justified? Has the advanced controller been tuned to its full capacity? Can this improvement also be achieved by simply retuning the existing traditional (e.g., PID) controllers? (see ► PID Control). In other words, what is the cost versus benefit of implementing an advanced controller? Unlike performance assessment using minimum variance control as benchmark, the solution to this problem does not require a priori knowledge of time delays. Two possible relative benchmarks may be chosen: one is the historical data benchmark or reference data set benchmark, and the other is a user-specified benchmark.

The purpose of reference data set benchmarking is to compare performance of the existing controller with the previous controller during the "normal" operation of the process. This reference data set may represent the process when the controller performance is considered satisfactory with respect to meeting the performance objectives. The reference data set should be representative of the normal conditions that the process is expected to operate at; i.e., the disturbances and set-point changes entering into the process should not be unusually different. This analysis provides the user with a relative performance index (RPI) which compares the existing control loop performance with a reference control loop benchmark chosen by the user. The RPI is bounded by $0 \leq RPI \leq \infty$, with "<1" indicating deteriorated performance, "1" indicating no change of performance, and ">1" indicating improved performance. Figure 6 shows a result of reference data set benchmarking. The impulse response of the benchmark or reference data smoothly decays to zero, indicating good performance of the controller. After one increases the proportional gain of the controller, the impulse response

shows oscillatory behavior, with an RPI = 0.4, indicating deteriorated performance due to the oscillation.

In some cases one may wish to specify certain desired closed-loop dynamics and carry out performance analysis with respect to such desired dynamics. One such desired dynamic benchmark is the closed-loop settling time. As an illustrative example, Fig. 8 shows a system where a settling time of ten sampling units is desired for a process with a delay of five sampling units. The impulse responses show that the existing loop is close to the desired performance, and the value of RPI = 0.9918 confirms this. Thus no further tuning of the loop is necessary.
Diagnosis of Poorly Performing Loops

Whereas detection of poorly performing loops is now relatively simple, the task of diagnosing reason(s) for poor performance and how to "mend" the loop is generally not straightforward. The reasons for poor performance could be any one of interactions between various control loops, overtuned or undertuned controller settings, process nonlinearity, poor controller configuration (meaning the choice of pairing a process (or controlled) variable with a manipulative variable loop), or actuator problems such as stiction, large delays, and severe disturbances. Several studies have focused on the diagnosis issues related to actuator problems (Håagglund 2002; Choudhury et al. 2008; Srinivasan and Rengaswamy 2008; Xiang and Lakshminarayanan 2009; de Souza et al. 2012). Shardt et al. (2012) has given an overview of the overall state of CPM and the related diagnosis issues.

Industrial Applications of CPM Technology

As remarked earlier, CPM software is now readily available from most DCS vendors and has already been implemented successfully at several large-scale industrial sites. A summary of just

two of many large-scale industrial implementations of CPM technology appears below. It gives a clear evidence of the impact of this control technology and how readily it has been embraced by industry (Shah et al. 2014).

BASF Controller Performance Monitoring Application

As part of its excellence initiative OPAL 21 (Optimization of Production Antwerp and Ludwigshafen), BASF has implemented the CPM strategy on more than 30,000 control loops at its Ludwigshafen site in Germany and on over 10,000 loops at its Antwerp production facility in Belgium. The key factor in using this technology effectively is to combine process knowledge, basic chemical engineering, and control expertise to develop solutions for the indicated control problems that are diagnosed in the CPM software (Wolff et al. 2012).

Saudi Aramco Controller Performance Monitoring Practice

As part of its process control improvement initiative, Saudi Aramco has deployed CPM on approximately 15,000 PID loops, 50 MPC applications, and 500 smart positioners across multiple operating facilities.

The operational philosophy of the CPM engine is incorporated in the continuous improvement process at BASF and Aramco, whereby all loops are monitored in real-time and a holistic performance picture is obtained for the entire plant. Unit-wide performance metrics are displayed in effective color-coded graphic forms to effectively convey the analytics information of the process.

Concluding Remarks

In summary, industrial control systems are designed and implemented or upgraded with a particular objective in mind. The controller performance monitoring methodology discussed here will permit automated and repeated reviews of the design, tuning, and upgrading of the control loops. Poor design, tuning, or upgrading of the control loops can be detected, and repeated performance monitoring will indicate which loops should be retuned or which loops have not been effectively upgraded when changes in the disturbances, in the process, or in the controller itself occur. Obviously better design, tuning, and upgrading will mean that the process will operate at a point close to the economic optimum, leading to energy savings, improved safety, efficient utilization of raw materials, higher product yields, and more consistent product qualities. This entry has summarized the major features available in recent commercial software packages for control loop performance assessment. The illustrative examples have demonstrated the applicability of this new technique when applied to process data.

This entry has also illustrated how controllers, whether in hardware or software form, should be treated like "capital assets" and how there should be routine monitoring to ensure that they perform close to the economic optimum and that the benefits of good regulatory control will be achieved.

Cooperative Manipulators

Fabrizio Caccavale
School of Engineering, Università degli Studi della Basilicata, Potenza, Italy

Abstract

This chapter presents an overview of the main issues related to modeling and control of cooperative robotic manipulators. A historical path is followed to present the main research results on cooperative manipulation. Kinematics and dynamics of robotic arms cooperatively manipulating a tightly grasped rigid object are briefly discussed. Then, this entry presents the main strategies for force/motion control of the cooperative system.

Keywords

Introduction

Since the early 1970s, it has been recognized that many tasks, which are difficult or even impossible to execute by a single robotic manipulator, become feasible when two or more manipulators work in a cooperative way. Examples of typical cooperative tasks are the manipulation of heavy and/or large payloads, assembly of multiple parts, and handling of flexible and articulated objects (Fig. 1).

In the 1980s, research achieved several theoretical results related to modeling and control of to single-arm robots; this further fostered research on multi-arm robotic systems. Dynamics

Cooperative Manipulators, Fig. 1 An example of a cooperative robotic work cell composed by two industrial robot arms

and control as well as force control issues have been widely explored along the decade.

In the 1990s, parameterization of the constraint forces/moments acting on the object has been recognized as a key to solving control problems and has been studied in several papers (e.g., Sang et al. 1995; Uchiyama and Dauchez 1993; Walker et al. 1991; Williams and Khatib 1993). Several control schemes for cooperative manipulators based on the sought parameterizations have been designed, including force/motion control (Wen and Kreutz-Delgado 1992) and impedance control (Bonitz and Hsia 1996; Schneider and Cannon 1992). Other approaches are adaptive control (Hu et al. 1995), kinematic control (Chiacchio et al. 1996), task-space regulation (Caccavale et al. 2000), and model-based coordinated control (Hsu 1993). Other important topics investigated in the 1990s were the definition of user-oriented task-space variables for coordinated control (Caccavale et al. 2000; Chiacchio et al. 1996), the development of meaningful performance measures (Chiacchio et al. 1991a,b) for multi-arm systems, and the problem of load sharing (Walker et al. 1989).

Most of the abovementioned works assume that the cooperatively manipulated object is rigid and tightly grasped. However, since the 1990s, several research efforts have been focused on the control of cooperative flexible manipulators (Yamano et al. 2004), since flexible-arm robot merits (lightweight structure, intrinsic compliance, and hence safety) can be conveniently exploited in cooperative manipulation. Other research efforts have been focused on the control of cooperative systems for the manipulation of flexible objects (Yukawa et al. 1996) as well.

Modeling, Load Sharing, and Performance Evaluation

The first modeling goal is the definition of suitable variables describing the kinetostatics of a cooperative system. Hereafter, the main results available are summarized for a dual-arm system

composed by two cooperative manipulators grasping a common object.

The kinetostatic formulation proposed by Uchiyama and Dauchez (1993), i.e., the so-called *symmetric formulation*, is based on kinematic and static relationships between generalized forces/velocities acting at the object and their counterparts acting at the manipulators end effectors. To this aim, the concept of *virtual stick* is defined as the vector which determines the position of an object-fixed coordinate frame with respect to the frame attached to each robot end effector (Fig. 2). When the object grasped by the two manipulators can be considered rigid and tightly attached to each end effector, then the virtual stick behaves as a rigid stick fixed to each end effector.

According to the symmetric formulation, the vector, h, collecting the generalized forces (i.e., forces and moments) acting at each end effector is given by

$$h = W^\dagger h_E + V h_I, \qquad (1)$$

where W is the so-called *grasp matrix*, the columns of V span the null space of the
Cooperative Manipulators, Fig. 2 Grasp geometry for a two-manipulator cooperative system manipulating a common object. The vectors r_1 and r_2 are the *virtual sticks*, $\mathcal{T}_c$ is the coordinate frame attached to the object, and $\mathcal{T}_1$ and $\mathcal{T}_2$ are the coordinate frames attached to each end effector

grasp matrix, and h_I is the generalized force vector which does not contribute to the object's motion, i.e., it represents internal loading of the object (mechanical stresses) and is termed as *internal forces*, while h_E represents the vector of *external forces*, i.e., forces and moments causing the object's motion. Later, a *task-oriented formulation* has been proposed (Chiacchio et al. 1996), aimed at defining a *cooperative task space* in terms of *absolute* and *relative* motion of the cooperative system, which can be directly computed from the position and orientation of the end-effector coordinate frames.

The dynamics of a cooperative multi-arm system can be written as the dynamics of the single manipulators together with the closed-chain constraints imposed by the grasped object. By eliminating the constraints, a reduced-order model can be obtained (Koivo and Unseren 1991).

Strongly related to kinetostatics and dynamics of cooperative manipulators is the load sharing problem, i.e., distributing the load among the arms composing the system, which has been solved, e.g., in Walker et al. (1989). A very relevant problem related to the load sharing is that of robust holding, i.e., the problem of determining forces/moments applied to object by the arms, in order to keep the grasp even in the presence of disturbing forces/moments.

A major issue in robotic manipulation is the performance evaluation via suitably defined indexes (e.g., manipulability ellipsoids). These concepts have been extended to multi-arm robotic systems in Chiacchio et al. (1991a,b). Namely, by exploiting the kinetostatic formulations described above, velocity and force manipulability ellipsoids can be defined, by regarding the whole cooperative system as a mechanical transformer from the joint space to the cooperative task space. The manipulability ellipsoids can be seen as performance measures aimed at determining the attitude of the system to cooperate in a given configuration.

Finally, it is worth mentioning the strict relationship between problems related to grasping of objects by fingers/hands and those related to cooperative manipulation. In fact, in both cases, multiple manipulation structures grasp a commonly manipulated object. In multifingered hands, only some motion components are transmitted through the contact point to the manipulated object (unilateral constraints), while cooperative manipulation via robotic arms is achieved by rigid (or near-rigid) grasp points and interaction takes place by transmitting all the motion components through the grasping points (bilateral constraints). While many common problems between the two fields can be tackled in a conceptually similar way (e.g., kinetostatic modeling, force control), many others are specific of each of the two application fields (e.g., form and force closure for multifingered hands).

Control

When a cooperative multi-arm system is employed for the manipulation of a common object, it is important to control both the absolute motion of the object and the internal stresses applied to it. Hence, most of the control approaches to cooperative robotic systems can be classified as force/motion control schemes.

Early approaches to the control of cooperative systems were based on the *master/slave* concept. Namely, the cooperative system is decomposed in a position-controlled master arm, in charge of imposing the absolute motion of the object, and the force-controlled slave arms, which are to follow (as smoothly as possible) the motion imposed by the master. A natural evolution of the above-described concept has been the so-called *leader/follower* approach, where the follower arm reference motion is computed via closed-chain constraints. However, such approaches suffered from implementation issues, mainly due to the fact that the compliance of the slave arms has to be very large, so as to smoothly follow the motion imposed by the master arm. Moreover, the roles of the master and slave (leader and follower) may need to be changed during the task execution.

Due to the abovementioned limitations, more natural nonmaster/slave approaches have been pursued later, where the cooperative system is seen as a whole. Namely, the reference motion

of the object is used to determine the motion of all the arms in the system and the interaction forces are measured and fed back so as to be directly controlled. To this aim, the mappings between forces and velocities at the end effector of each manipulator and their counterparts at the manipulated object are considered in the design of the control laws.

An approach, based on the classical hybrid force/position control scheme, has been proposed in Uchiyama and Dauchez (1993), by exploiting the symmetric formulation described in the previous section.

In Wen and Kreutz-Delgado (1992) a Lyapunov-based approach is pursued to devise force/position PD-type control laws. This approach has been extended in Caccavale et al. (2000), where kinetostatic filtering of the control action is performed, so as to eliminate all the components of the control input which contribute to internal stresses at the object.

A further improvement of the PD plus gravity compensation control approach has been achieved by introducing a full model compensation, so as to achieve feedback linearization of the closed-loop system. The feedback linearization approach formulated at the operational space level is the base of the so-called *augmented object* approach (Sang et al. 1995). In this approach, the system is modeled in the operational space as a whole, by suitably expressing its inertial properties via a single augmented inertia matrix M_O, i.e.,

$$M_O(x_E)\ddot{x}_E + c_O(x_E, \dot{x}_E) + g_O(x_E) = h_E, \quad (2)$$

where M_O, c_O, and g_O are the operational space terms modeling, respectively, the inertial properties of the whole system (manipulators and object), the Coriolis/centrifugal/friction terms, and the gravity terms, while x_E is the operational space vector describing the position and orientation of the coordinate frame attached to the grasped object. In the framework of feedback linearization (formulated in the operational space), the problem of controlling the internal forces can be solved, e.g., by resorting to the *virtual linkage*

model (Williams and Khatib 1993) or according to the scheme proposed in Hsu (1993).

An alternative control approach is based on the well-known impedance concept (Bonitz and Hsia 1996; Schneider and Cannon 1992). In fact, when a manipulation system interacts with an external environment and/or other manipulators, large values of the contact forces and moments can be avoided by enforcing a compliant behavior with suitable dynamic features. In detail, the following mechanical impedance behavior between the object displacements and the forces due to the object-environment interaction can be enforced (*external impedance*):

$$M_E \tilde{a}_E + D_E \tilde{v}_E + K_e e_E = h_{\text{env}}, \quad (3)$$

where e_E represents the vector of displacements between object's desired and actual pose, $\tilde{v}_E$ is the difference between the object's desired and actual generalized velocities, $\tilde{a}_E$ is the difference between the object's desired and actual generalized accelerations, and h_{env} is the generalized force acting on the object, due to the interaction with the environment. The impedance dynamics is characterized in terms of given positive definite mass, damping, and stiffness matrices (M_E, D_E, K_E). A mechanical impedance behavior between the ith end-effector displacements and the internal forces can be imposed as well (*internal impedance*):

$$M_{I,i} \tilde{a}_i + D_{I,i} \tilde{v}_i + K_{I,i} e_i = h_{I,i}, \quad (4)$$

where e_i is the vector expressing the displacement between the commanded and the actual pose of the ith end effector, $\tilde{v}_i$ is the vector expressing the difference between commanded and actual generalized velocities of the ith end effector, $\tilde{a}_i$ is the vector expressing the difference between commanded and actual generalized accelerations of the ith end effector, and $h_{I,i}$ is the contribution of the ith end effector to the internal force. Again, the impedance dynamics is characterized in terms of given positive definite mass, damping, and stiffness matrices ($M_{I,i}, D_{I,i}, K_{I,i}$). More recently, an impedance scheme for control

of both external forces and internal forces has
been proposed (Caccavale et al. 2008).

Summary and Future Directions

This entry has provided a brief survey of the
main issues related to cooperative robots, with
special emphasis on modeling and control prob-
lems. Among several open research topics in
cooperative manipulation, it is worth mentioning
the problem of cooperative transportation and
manipulation of objects via multiple mobile ma-
nipulators. In fact, although notable results have
been already devised in Khatib et al. (1996),
the foreseen use of robotic teams in industrial
settings (hyperflexible robotic work cells) and/or
in collaboration with humans (robotic coworker
concept) raises new challenges related to auton-
omy and safety of multiple mobile manipulators.
Also, an emerging application field is given by
cooperative systems composed by multiple aerial
vehicle-manipulator systems (see, e.g., Fink et al.
2011).

Cooperative Solutions to Dynamic Games

Alain Haurie
ORDECSYS and University of Geneva, Switzerland
GERAD-HEC Montréal PQ, Canada

Abstract

This article presents the fundamental elements of the theory of cooperative games in the context of dynamic systems. The concepts of Pareto optimality, Nash bargaining solution, characteristic function, cores, and C-optimality are discussed, and some fundamental results are recalled.

Keywords

Introduction

Solution concepts in game theory are regrouped in two main categories called noncooperative and cooperation solutions, respectively. In the seminal book of von Neumann and Morgen-

stern (1944) this categorization is already made. These authors discuss zero-sum (matrix) games in normal form, where the noncooperative solution concept of saddle-point was defined and characterized, and games in characteristic function form, where solution concepts for games of coalitions were introduced. In this article we present the fundamental solution concepts of the theory of cooperative games in the context of dynamical systems. The article is organized as follows: we first recall the papers, which mark the origin of development of a theory of dynamic games; then we recall the basic concept of Pareto optimality proposed as a cooperative solution concept; we present the scalarization technique and the necessary or sufficient optimality conditions for Pareto optimality in mathematical programming and optimal control settings; we then explore the difficulties encountered when one tried to extend the Nash bargaining solution, characteristic function and cores concept to dynamic games; we show the links that exist with the theory of reachability for perturbed dynamic systems.

The Origins

One may consider that the first introduction of a cooperative game solution concept in systems and control science is due to L.A. Zadeh (1963). Two-player zero-sum dynamic games have been studied by R. Isaacs (1954) in a deterministic continuous time setting and by L. Shapley (1953) in a discrete time stochastic setting. Nonzero-sum and m player differential games were introduced by Y.C. Ho and A.W. Starr (1969) and J.H. Case (1969). For these games cooperative solutions can be looked for to complement the noncooperative Nash equilibrium concept.

Cooperation Solution Concept

In cooperative games one is interested in non-dominated solution. This solution type is related to a concept introduced by the well-known economist V. Pareto (1869) in the context of

welfare economics. Consider a system with decision variables $x \in X \subset \mathbb{R}^n$ and m performance criteria $x \to \psi_j(x) \in \mathbb{R}$, $j = 1, \ldots, m$ that one tries to maximize.

Definition 1 The decision $x^* \in X$ is nondominated or Pareto optimal if the following condition holds:

$$\psi_j(x) \geq \psi_j(x^*) \quad \forall j = 1, \ldots m$$
$$\implies \psi_j(x) = \psi_j(x^*) \quad \forall j = 1, \ldots m.$$

In other words it is impossible to give one criterion j a value greater than $\psi_j(x^*)$ without decreasing the value of another criterion, say ℓ, which then takes a value lower than $\psi_\ell(x^*)$.

This vector-valued optimization framework corresponds to a situation where m players are engaged in a game, described in its normal form, where the strategies of the m players constitute the decision vector x and their respective payoffs are given by the m performance criteria $\psi_j(x)$, $j = 1, \ldots, m$. One assumes that these players jointly take a decision that is cooperatively optimal, in the sense that no player can improve his/her payoff without deteriorating the payoff of at least one other player.

The Scalarization Technique

Let $\mathbf{r} = (r_1, r_2, \ldots, r_m)$ be a given m-vector composed of normalized weights that satisfy $r_j > 0$, $j = 1 \ldots, m$ and $\sum_{j=1,\ldots,m} r_j = 1$.

Lemma 1 *Let $x^* \in X$ be a maximum in X for the scalarized criterion $\Psi(x; \mathbf{r}) = \sum_{j=1}^m r_j \psi_j(x)$. Then x^* is a nondominated solution for the multi-objective problem.*

The proof is very simple. Suppose x^* is dominated, then there exists $x^\circ \in X$ such that $\psi_j(x^\circ) \geq \psi_j(x^*)$, $\forall j = 1, \ldots, m$, and $\psi_i(x^\circ) > \psi_i(x^*)$ for one $i \in \{1, \ldots, m\}$. Since all the r_j are > 0, this yields $\sum_{j=1}^m r_j \psi_j(x^\circ) > \sum_{j=1}^m r_j \psi_j(x^*)$, which contradicts the maximizing property of x^*. This result shows that it will be very easy to find many Pareto optimal solutions by varying a strictly positive weighting

of the criteria. But this procedure will not find all of the nondominated solutions.

Conditions for Pareto Optimality in Mathematical Programming

N.O. Da Cunha and E. Polak (1967b) have obtained the first necessary conditions for multiobjective optimization. The problem they consider is

$$\text{Pareto Opt. } \psi_j(x) \quad j = 1, \ldots m$$
$$\text{s.t.}$$
$$\varphi_k(x) \leq 0 \quad k = 1, \ldots p$$

where the functions $x \in \mathbb{R}^n \mapsto \psi_j(x) \in \mathbb{R}$, $j = 1, \ldots, m$, and $x \mapsto \varphi_k(x) \in \mathbb{R}$, $k = 1, \ldots, p$ are continuously differentiable (C^1) and where we assume that the constraint qualification conditions of mathematical programming hold for this problem too. They proved the following theorem.

Theorem 1 *Let x^* be a Pareto optimal solution of the problem defined above. Then there exists a vector λ of p multipliers λ_k, $k = 1, \ldots, p$, and a vector $\mathbf{r} \neq 0$ of m weights $r_j \geq 0$, such that the following conditions hold*

$$\frac{\partial}{\partial x} \mathcal{L}\left(x^*; \mathbf{r}; \lambda\right) = 0$$
$$\varphi_k(x^*) \leq 0$$
$$\lambda_k \varphi_k(x^*) = 0$$
$$\lambda_k \geq 0,$$

where $\mathcal{L}\left(x^*; \mathbf{r}; \lambda\right)$ is the weighted Lagrangian defined by

$$\mathcal{L}\left(x; \mathbf{r}; \lambda\right) = \sum_{j=1}^m r_j \psi_j(x) + \sum_{k=1}^p \lambda_k \varphi_k(x).$$

So there is a local scalarization principle for Pareto optimality.

Maximum Principle

The extension of Pareto optimality concept to control systems was done by several authors (Basile and Vincent 1970; Bellassali and Jourani 2004; Binmore et al. 1986; Blaquière et al. 1972;

Leitmann et al. 1972; Salukvadze 1971; Vincent and Leitmann 1970; Zadeh 1963), the main result being an extension of the maximum principle of Pontryagin. Let a system be governed by state equations:

$$\dot{x}(t) = f(x(t), u(t)) \tag{1}$$

$$u(t) \in U \tag{2}$$

$$x(0) = x_o \tag{3}$$

$$t \in [0, T] \tag{4}$$

where $x \in \mathbb{R}^n$ is the state variable of the system, $u \in U \subset \mathbb{R}^p$ with U compact is the control variable, and $[0, T]$ is the control horizon. The system is evaluated by m performance criteria of the form

$$\psi_j(x(\cdot), u(\cdot)) = \int_0^T g_j(x(t), u(t)) dt + G_j(x(T)), \tag{5}$$

for $j = 1, \ldots, m$. Under the usual assumptions of control theory, i.e., $f(\cdot, \cdot)$ and $g_j(\cdot, \cdot)$, $j = 1, \ldots, m$, being C^1 in x and continuous in u, $G_j(\cdot)$ being C^1 in x, one can prove the following.

Theorem 2 *Let $\{x^*(t) : t \in [0, T]\}$ be a Pareto optimal trajectory, generated at initial state x° by the Pareto optimal control $\{u^*(t) : t \in [0, T]\}$. Then there exist costate vectors $\{\lambda^*(t) : t \in [0, T]\}$ and a vector of positive weights $\mathbf{r} \neq 0 \in \mathbb{R}^m$, with components $r_j \geq 0$, $\sum_{j=1}^m r_j = 1$, such that the following relations hold:*

$$\dot{x}^*(t) = \frac{\partial}{\partial \lambda} H(x^*(t), u^*(t); \lambda(t); \mathbf{r}) \tag{6}$$

$$\dot{\lambda}(t) = -\frac{\partial}{\partial x} H(x^*(t), u^*(t); \lambda(t); \mathbf{r}) \tag{7}$$

$$x^*(0) = x_o \tag{8}$$

$$\lambda(T) = \sum_{j=1}^m r_j \frac{\partial}{\partial x} G_j(x(T)) \tag{9}$$

with

$$H(x^*(t), u^*(t); \lambda(t); \mathbf{r})$$
$$= \max_{u \in U} H(x^*(t), u; \lambda(t); \mathbf{r})$$

where the weighted Hamiltonian is defined by

$$H(x, u; \lambda; \mathbf{r}) = \sum_{j=1}^m r_j \, g_j(x, u) + \lambda^T \, f(x, u).$$

The proof of this result necessitates some additional regularity assumptions. Some of these conditions imply that there exist differentiable Bellman value functions (see, e.g., Blaquière et al. 1972); some others use the formalism of nonsmooth analysis (see, e.g., Bellassali and Jourani 2004).

The Nash Bargaining Solution

Since Pareto optimal solutions are numerous (actually since a subset of Pareto outcomes are indexed over the weightings $\mathbf{r}$, $r_j > 0$, $\sum_{j=1}^m r_j = 1$), one can expect, in the payoff m-dimensional space, to have a manifold of Pareto outcomes. Therefore, the problem that we must solve now is *how to select the "best" Pareto outcome*? "Best" is a misnomer here, because, by their very definition, two Pareto outcomes cannot be compared or gauged. The choice of a Pareto outcome that satisfies each player must be the result of some bargaining. J. Nash addressed this problem very early, in 1951, using a two-player game setting. He developed an axiomatic approach where he proposed four behavior axioms which, if accepted, would determine a unique choice for the bargaining solution. These axioms are called respectively, (i) invariance to affine transformations of utility representations, (ii) Pareto optimality, (iii) independence of irrelevant alternatives, and (iv) symmetry. Then the bargaining point is the Pareto optimal solution that maximizes the product

$$x^* = \text{argmax}_x (\psi_1(x) - \psi_1(x^\circ))(\psi_2(x) - \psi_2(x^\circ))$$

where x° is the status quo decision, in case bargaining fails, and $(\psi_j(x^\circ))$, $j = 1, 2$ are the payoffs associated with this no-accord decision (this defines the so-called threat point). It has been proved (Binmore et al. 1986) that this

solution could be obtained also as the solution of an auxiliary dynamic game in which a sequence of claims and counterclaims is made by the two players when they bargain.

When extended directly to the context of differential or multistage games, the Nash bargaining solution concept proved to lack the important property of time consistency. This was first noticed in Haurie (1976). Let a dynamic game be defined by Eqs. (1)–(5), with $j = 1, 2$. Suppose the status quo decision, if no agreement is reached at initial state $(t = 0, x(0) = x^o)$, consists in playing an open-loop Nash equilibrium, defined by the controls $u_j^N(\cdot) : [0, T] \to U_j$, $j = 1, 2$ and generating the trajectory $x^N(\cdot) : [0, T] \to \mathbb{R}^n$, with $x^N(0) = x_o$. Now applying the Nash bargaining solution scheme to the data of this differential game played at time $t = 0$ and state $x(0) = x_o$, one identifies a particular Pareto optimal solution, associated with the controls $u^*(\cdot) : [0, T] \to U_j$, $j = 1, 2$ and generating the trajectory $x^*(\cdot) : [0, T] \to \mathbb{R}^n$, with $x^*(0) = x_o$. Now assume the two players renegotiate the agreement to play $u_j^*(\cdot)$ at an intermediate point of the Pareto optimal trajectory $(\tau, x^*(\tau))$, $\tau \in (0, T)$. When computed from that point, the status quo strategies are in general not the same as they were at $(0, x_o)$; furthermore, the shape of the Pareto frontier, when the game is played from $(\tau, x^*(\tau))$, is different from what it is when the game is played at $(0, x_o)$. For these two reasons the bargaining solution at $(\tau, x^*(\tau))$ will not coincide in general with the restriction to the interval $[\tau, T]$ of the bargaining solution from $(0, x_o)$. This implies that the solution concept is not *time consistent*. Using feedback strategies, instead of open-loop ones, does not help, as the same phenomena (change of status quo and change of Pareto frontier) occur in a feedback strategy context.

This shows that the cooperative game solutions proposed in the classical theory of games cannot be applied without precaution in a dynamic setting when players have the possibility to renegotiate agreements at any intermediary point $(t, x^*(t))$ of the bargained solution trajectory.

Cores and C-Optimality in Dynamic Games

Characteristic functions and the associated solution concept of core are important elements in the classical theory of cooperative games. In two papers (Haurie 1975; Haurie and Delfour 1974) the basic definitions and properties of the concept of core in dynamic cooperative games were presented. Consider the multistage system, controlled by a set M of m players and defined by

$$x(k + 1) = f^k(x(k), u_M(k)),$$
$$k = 0, 1, \ldots, K - 1$$
$$x(i) = x^i, \ i \in \{0, 1, \ldots, K - 1\}$$
$$u_M(k) \triangleq (u_j(k))_{j \in M} \in U_M(k) \triangleq \prod_{j \in M} U_j(k).$$

From the initial point (i, x^i) a control sequence $(u_M(i), \ldots, u_M(K - 1))$ generates for each player j a payoff defined as follows:

$$J_j(i, x^i; u_M(i), \ldots, u_M(K - 1)) \triangleq$$
$$\sum_{k=i}^{K-1} \Phi_j(x(k), u_M(k)) + \Upsilon_j(x(K)).$$

A subset S of M is called a coalition. Let $\mu_S^k : x(k) \mapsto u_S(k) \in \prod_{j \in S} U_j(k)$ be a feedback control for the coalition defined at each stage k. A player $j \in S$ considers then, from any initial point (i, x^i), his guaranteed payoff:

$$\Psi_j(i, x^i; \mu_S^i, \ldots, \mu_S^{K-1}) \triangleq$$
$$\inf_{u_{M-s}(i) \in U_{M-s}(i), \ldots, u_{M-s}(K-1) \in U_{M-s}(K-1)}$$
$$\sum_{k=i}^{K-1} \Phi_j(x(k), [\mu_S^k(x(k)), u_{M-S}(k)])$$
$$+ \Upsilon_j(x(K)).$$

Definition 2 The characteristic function at stage i for coalition $S \subset M$ is the mapping $v^i : (S, x^i) \mapsto v^i(S, x^i) \subset \mathbb{R}^S$ defined by

$$\omega_S \triangleq (\omega_j)_{j \in S} \in v^i(S, x^i) \Leftrightarrow$$

$$\exists \mu_S^i, \ldots, \mu_S^{K-1} : \forall j \in S$$

$$\Psi_j(i, x^i; \mu_S^i, \ldots, \mu_S^{K-1}) \geq \omega_j.$$

In other words, there is a feedback law for the coalition S which guarantees at least ω_j to each player j in the coalition.

Suppose that in a cooperative agreement, at point (i, x^i), the coalition S is proposed a gain vector ω_s which is interior to $v^i(S, x^i)$. Then coalition S will block this agreement, because using an appropriate feedback, the coalition can guarantee a better payoff to each of its members. We can now extend the definition of the core of a cooperative game to the context of dynamic games, as the set of agreement gains that cannot be blocked by any coalition.

Definition 3 The core $\Omega(i, x^i)$ at point (i, x^i) is the set of gain vectors $\omega_M \triangleq (\omega_j)_{j \in M}$ such that:
1. There exists a Pareto optimal control $u_M^\star(i), \ldots, u_M^\star(K-1)$ for which $\omega_j = J_j(i, x^i; u_M^\star(i), \ldots, u_M^\star(K-1))$,
2. $\forall S \subset M$ the projection of ω_M in $\mathbb{R}^S$ is not interior to $v^i(S, x^i)$

Playing a cooperative game, one would be interested in finding a solution where the gain-to-go remains in the core at each point of the trajectory. This leads us to define the following.

Definition 4 A control $\tilde{u}^o \triangleq (u_M^o(0), \ldots, u_M (K-1))$ is C-optimal at $(0, x^0)$ if $\tilde{u}^o$ is Pareto optimal generating a state trajectory

$$\{x^o(0) = x^0, x^o(1), \ldots, x^o(K)\}$$

and a sequence of gain-to-go values

$$\omega_j^o(i) = J_j(i, x^o(i); u_M^o(i), \ldots, u_M^o(K-1)),$$
$$i = 0, \ldots, K-1$$

such that $\forall i = 0, 1, \ldots, K-1$, the m-vector $\omega_M^o(i)$ is element of the core $\Omega(i, x^o(i))$.

A C-optimal control generates an agreement which cannot be blocked by any coalition along the Pareto optimal trajectory. It can be shown on

examples that a Pareto optimal trajectory which has the gain-to-go vector in the core at initial point $(0, x_0)$ is not C-optimal.

Links with Reachability Theory for Perturbed Systems

The computation of characteristic functions can be made using the techniques developed to study reachability of dynamic systems with set constrained disturbances (see Bertsekas and Rhodes 1971). Consider the particular case of a linear system

$$x(k+1) = A^k x(k) + \sum_{j \in M} B_j^k u_j(k) \quad (10)$$

where $x \in \mathbb{R}^n$, $u_j \in U_j^k \subset \mathbb{R}^{p_j}$, where U_j^k is a convex-bound set and A^k, B_j^k are matrices of appropriate dimensions. Let the payoff to player j be defined by:

$$J_j(i, x^i; u_M(i), \ldots, u_M(K-1)) \triangleq$$

$$\sum_{k=i}^{K-1} \phi_j^k(x(k)) + \gamma_j^k(u_j(k)) + \Upsilon_j(x(K)).$$

Algorithm Here we use the notations $\phi_S^k \triangleq (\phi_j^k)_{j \in S}$ and $B_S^k u_S \triangleq \sum_{j \in S} B_j^k u_j$. Also we denote $\{u + V\}$, where u is a vector in $\mathbb{R}^m$ and $V \subset \mathbb{R}^m$, the set of vectors $u + v$, $\forall v \in V$. Then
1. $\forall x^K \ v^K(S, x^K) \triangleq \{\omega_S \in \mathbb{R}^S : \Upsilon_S(x^K) \geq \omega_S\}$
2. $\forall x \ \mathcal{E}^{k+1}(S, x) \triangleq \cap v \in U_{M-S} \ v^{k+1}$
   $(S, x + B_{M_S}^k v)$
3. $\forall x^k \ \mathcal{H}^k(S, x^k) \triangleq \underset{u \in U_S}{\cup} \{\gamma_S^k(u) + \mathcal{E}^{k+1}$
   $(S, A^k x^k + B_S^k u)\}$
4. $\forall x^k \ v^k(S, x^k) = \{\phi_S^k(x^k) + \mathcal{H}^k(S, x^k)\}.$
   In an open-loop control setting, the calculation of characteristic function can be done using the concept of Pareto optimal solution for a system with set constrained disturbances, as shown in Goffin and Haurie (1973, 1976) and Haurie (1973).

Conclusion

Since the foundations of a theory of cooperative solutions to dynamic games, recalled in this article, the research has evolved toward the search for cooperative solutions that could be also equilibrium solution, using for that purpose a class of memory strategies Haurie and Towinski (1985), and has found a very important domain of application in the assessment of environmental agreements, in particular those related to the climate change issue. For example, the sustainability of solutions in the core of a dynamic game modeling international environmental negotiations is studied in Germain et al. (2003). A more encompassing model of dynamic formation of coalitions and stabilization of solutions through the use of threats is proposed in Breton et al. (2010). These references are indicative of the trend of research in this field.

Coordination of Distributed Energy Resources for Provision of Ancillary Services: Architectures and Algorithms

Alejandro D. Domínguez-García[1] and
Christoforos N. Hadjicostis[2]
[1]University of Illinois at Urbana-Champaign,
Urbana-Champaign, IL, USA
[2]University of Cyprus, Nicosia, Cyprus

Abstract

We discuss the utilization of distributed energy resources (DERs) to provide active and reactive power support for ancillary services. Though the amount of active and/or reactive power provided individually by each of these resources can be very small, their presence in large numbers in power distribution networks implies that, under proper coordination mechanisms, they can collectively provide substantial active and reactive power regulation capacity. In this entry, we provide a simple formulation of the DER coordination problem for enabling their utilization to provide ancillary services. We also provide specific architectures and algorithmic solutions to solve the DER coordination problem, with focus on decentralized solutions.

Keywords

Ancillary services; Consensus; Distributed algorithms; Distributed energy resources (DERs)

Introduction

On the distribution side of a power system, there are many distributed energy resources (DERs), e.g., photovoltaic (PV) installations, plug-in hybrid electric vehicles (PHEVs), and thermostatically controlled loads (TCLs), that can be potentially used to provide ancillary services, e.g., reactive power support for voltage control (see, e.g., Turitsyn et al. (2011) and the references therein) and active power up and down regulation for frequency control (see, e.g., Callaway and Hiskens (2011) and the references therein). To enable DERs to provide ancillary services, it is necessary to develop appropriate control and coordination mechanisms. One potential solution relies on a centralized control architecture in which each DER is directly coordinated by (and communicates with) a central decision maker. An alternative approach is to distribute the decision making, which obviates the need for a central decision maker to coordinate the DERs. In both cases, the decision making involves solving a *resource allocation* problem for coordinating the DERs to collectively provide a certain amount of a resource (e.g., active or reactive power).

In a practical setting, whether a centralized or a distributed architecture is adopted, the control of DERs for ancillary services provision will involve some aggregating entity that will gather together and coordinate a set of DERs, which will provide certain amount of active or reactive power in exchange for monetary benefits. In general, these aggregating entities are the ones that interact with the ancillary services market, and through some market-clearing mechanism, they enter a contract to provide some amount of resource, e.g., active and/or reactive power over a period of time. The goal of the aggregating entity is to provide this amount of resource by properly coordinating and controlling the DERs, while ensuring that the total monetary compensation to the DERs for providing the resource is below the monetary benefit that the aggregating entity obtains by selling the resource in the ancillary services market.

In the context above, a household with a solar PV rooftop installation and a PHEV might choose to offer the PV installation to a renewable aggregator so it is utilized to provide reactive power support (this can be achieved as long as the PV installation power electronics-based grid interface has the correct topology Domínguez-García et al. 2011). Additionally, the household could offer its PHEV to a battery vehicle aggregator to be used as a controllable load for energy peak shaving during peak hours and load leveling at night (Guille and Gross 2009).

Finally, the household might choose to enroll in a demand response program in which it allows a demand response provider to control its TCLs to provide frequency regulation services (Callaway and Hiskens 2011). In general, the renewable aggregator, the battery vehicle aggregator, and the demand response provider can be either separate entities or they can be the same entity. In this entry, we will refer to these aggregating entities as *aggregators*.

The Problem of DER Coordination

Without loss of generality, denote by x_j the amount of resource provided by DER i without specifying whether it is active or reactive power. [However, it is understood that each DER provides (or consumes) the same type of resource, i.e., all the x_i's are either active or reactive power.] Let $0 < \underline{x}_i < \overline{x}_i$, for $i = 1, 2, \ldots, n$, denote the minimum ($\underline{x}_i$) and maximum ($\overline{x}_i$) capacity limits on the amount of resource x_i that node i can provide. Denote by X the total amount of resource that the DERs must collectively provide to satisfy the aggregator request. Let $\pi_i(x_i)$ denote the price that the aggregator pays DER i per unit of resource x_i that it provides. Then, the objective of the aggregator in the DER coordination problem is to minimize the total monetary amount to be paid to the DERs for providing the total amount of resource X while satisfying the individual capacity constraints of the DERs. Thus, the DER coordination problem can be formulated as follows:

$$
\begin{aligned}
\text{minimize} \quad & \sum_{i=1}^{n} x_i \pi_i(x_i) \\
\text{subject to} \quad & \sum_{i=1}^{n} x_i = X \\
& 0 < \underline{x}_i \leq x_i \leq \overline{x}_i, \ \forall j.
\end{aligned} \tag{1}
$$

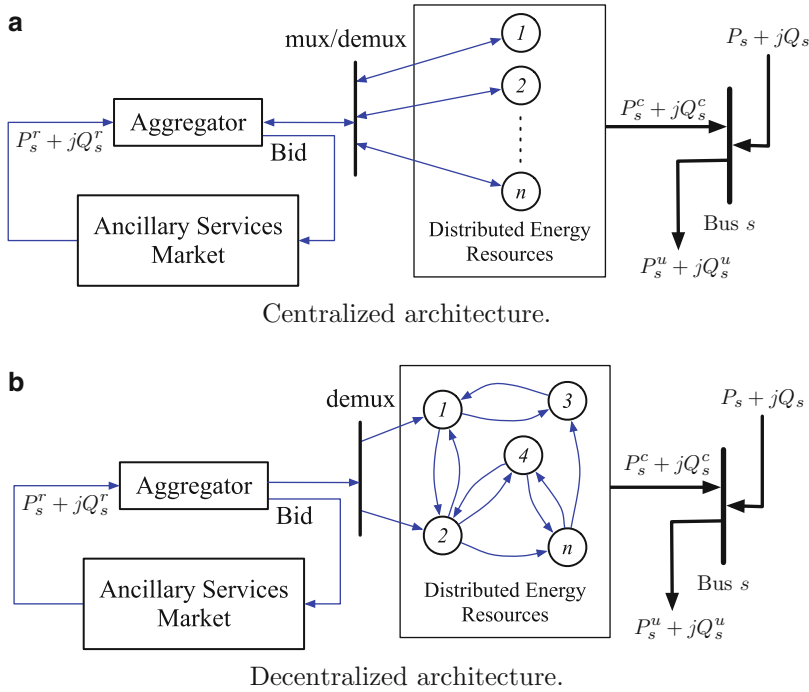
By allowing heterogeneity in the price per unit of resource that the aggregator offers to each DER, we can take into account the fact that the aggregator might value classes of DERs differently. For example, the downregulation capacity provided by a residential PV installation (which is achieved by curtailing its power) might be valued differently from the downregulation capacity provided by a TCL or a PHEV (both would need to absorb additional power in order to provide downregulation).

It is not difficult to see that if the price functions $\pi_i(\cdot)$, $i = 1, 2 \ldots, n$, are convex and nondecreasing, then the cost function $\sum_{i=1}^{n} x_i \pi_i(x_i)$ is convex; thus, if the problem in (1) is feasible, then there exists a globally optimal solution. Additionally, if the price per unit of resource is linear with the amount of resource, i.e., $\pi_i(x_i) = c_i x_i$, $i = 1, 2, \ldots, n$, then $x_i \pi_i(x_i) = c_i x_i^2$, $i = 1, 2, \ldots, n$, and the problem in (1) reduces to a quadratic program. Also, if the price per unit of resource is constant, i.e., $\pi_i(x_i) = c_i$, $i = 1, 2, \ldots, n$, then $x_i \pi_i(x_i) = c_i x_i$, $i = 1, 2, \ldots, n$, and the problem in (1) reduces to a linear program. Finally, if $\pi_i(x_i) = \pi(x_i) = c$, $i = 1, 2, \ldots, n$, for some constant $c > 0$, i.e., the price offered by the aggregator is constant and the same for all DERs, then the optimization problem in (1) becomes a feasibility problem of the form

$$
\begin{aligned}
\text{find} \quad & x_1, x_2, \ldots, x_n \\
\text{subject to} \quad & \sum_{i=1}^{n} x_i = X \\
& 0 < \underline{x}_i \leq x_i \leq \overline{x}_i, \ \forall j.
\end{aligned} \tag{2}
$$

If the problem in (2) is indeed feasible (i.e., $\sum_{l=1}^{n} \underline{x}_l \leq X \leq \sum_{l=1}^{n} \overline{x}_l$), then there is an infinite number of solutions. One such solution, which we refer to as *fair splitting*, is given by

$$
x_i = \underline{x}_i + \frac{X - \sum_{l=1}^{n} \underline{x}_l}{\sum_{l=1}^{n} (\overline{x}_l - \underline{x}_l)} (\overline{x}_i - \underline{x}_i), \ \forall i. \tag{3}
$$

The formulation to the DER coordination problem provided in (2) is not the only possible one. In this regard, and in the context of PHEVs, several recent works have proposed game-theoretic formulations to the problem (Gharesifard et al. 2013; Ma et al. 2013; Tushar et al. 2012). For example, in Gharesifard et al. (2013),


Coordination of Distributed Energy Resources for Provision of Ancillary Services: Architectures and Algorithms, Fig. 1 Control architecture alternatives. (**a**) Centralized architecture. (**b**) Decentralized architecture

the authors assume that each PHEV is a decision maker and can freely choose to participate after receiving a request from the aggregator. The decision that each PHEV is faced with depends on its own utility function, along with some pricing strategy designed by the aggregator. The PHEVs are assumed to be price anticipating in the sense that they are aware of the fact that the pricing is designed by the aggregator with respect to the average energy available. Another alternative is to formulate the DER coordination problem as a scheduling problem (Chen et al. 2012; Subramanian et al. 2012), where the DERs are treated as tasks. Then, the problem is to develop real-time scheduling policies to service these tasks.

Architectures

Next, we describe two possible architectures that can be utilized to implement the proper algorithms for solving the DER coordination problem

as formulated in (1). Specifically, we describe a centralized architecture that requires the aggregator to communicate bidirectionally with each DER and a distributed architecture that requires the aggregator to only unidirectionally communicate with a limited number of DERs but requires some additional exchange of information (not necessarily through bidirectional communication links) among the DERs.

Centralized Architecture

A solution can be achieved through the completely centralized architecture of Fig. 1a, where the aggregator can exchange information with each available DER. In this scenario, each DER can inform the aggregator about its active and/or reactive capacity limits and other operational constraints, e.g., maintenance schedule. After gathering all this information, the aggregator solves the optimization program in (1), the solution of which will determine how to allocate among the resources the total amount of active power P_s^r and/or reactive

power Q_s^r that it needs to provide. Then, the aggregator sends individual commands to each DER so they modify their active and or reactive power generation according to the solution of (1) computed by the aggregator. In this centralized solution, however, it is necessary to overlay a communication network connecting the aggregator with each resource and to maintain knowledge of the resources that are available at any given time.

Decentralized Architecture

An alternative is to use the decentralized control architecture of Fig. 1b, where the aggregator relays information to a limited number of DERs that it can directly communicate with and each DER is able to exchange information with a number of other close-by DERs. For example, the aggregator might broadcast the prices to be paid to each type of DER. Then, through some distributed protocol that adheres to the communication network interconnecting the DERs, the information relayed by the aggregator to this limited number of DERs is disseminated to all other available DERs. This dissemination process may rely on flooding algorithms, message-passing protocols, or linear-iterative algorithms as proposed in Domínguez-García and Hadjicostis (2010, 2011). After the dissemination process is complete and through a distributed computation over the communication network, the DERs can solve the optimization program in (1) and determine its active and/or reactive power contribution.

A decentralized architecture like the one in Fig. 1b may offer several advantages over the centralized one in Fig. 1b, including the following. First, a decentralized architecture may be more economical because it does not require communication between the aggregator and the various DERs. Also, a decentralized architecture does not require the aggregator to have a complete knowledge of the DERs available. Additionally, a decentralized architecture can be more resilient to faults and/or unpredictable behavioral patterns by the DERs. Finally, the practical implementation of such decentralized architecture can rely on inexpensive and simple hardware. For example,

the testbed described in Domínguez-García et al. (2012a), which is used to solve a particular instance of the problem in (1), uses Arduino microcontrollers (see Arduino for a description) outfitted with wireless transceivers implementing a ZigBee protocol (see ZigBee for a description).

Algorithms

Ultimately, whether a centralized or a decentralized architecture is adopted, it is necessary to solve the optimization problem in (1). If a centralized architecture is adopted, then solving (1) is relatively straightforward using, e.g., standard gradient-descent algorithms (see, e.g., Bertsekas and Tsitsiklis 1997). Beyond the DER coordination problem and the specific formulation in (1), solving an optimization problem is challenging if a decentralized architecture is adopted (especially if the communication links between DERs are not bidirectional); this has spurred significant research in the last few years (see, e.g., Bertsekas and Tsitsiklis 1997, Xiao et al. 2006, Nedic et al. 2010, Zanella et al. 2011, Gharesifard and Cortes 2012, and the references therein).

In the specific context of the DER coordination problem as formulated in (1), when the cost functions are assumed to be quadratic and the communication between DERs is not bidirectional, an algorithm amenable for implementation in a decentralized architecture like the one in Fig. 1b has been proposed in Domínguez-García et al. (2012a). Also, in the context of Fig. 1b, when the communication between DERs are bidirectional, the DER coordination problem, as formulated in (1), can be solved using an algorithm proposed in Kar and Hug (2012).

As mentioned earlier, when the price offered by the aggregator is constant and identical for all DERs, the problem in (1) reduces to the feasibility problem in (2). One possible solution to this feasibility problem is the fair-splitting solution in (3). Next, we describe a linear-iterative algorithm – originally proposed in Domínguez-García and Hadjicostis (2010, 2011) and referred to as *ratio consensus* – that allows the DERs to

individually determine its contribution so that the fair-splitting solution is achieved.

Ratio Consensus: A Distributed Algorithm for Fair Splitting

We assume that each DER is equipped with a processor that can perform simple computations and can exchange information with neighboring DERs. In particular, the information exchange between DERs can be described by a directed graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$, where $\mathcal{V} = \{1, 2, \ldots, n\}$ is the vertex set (each vertex – or node – corresponds to a DER) and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is the set of edges, where $(i, j) \in \mathcal{E}$ if node i can receive information from node j. We require $\mathcal{G}$ to be *strongly connected*, i.e., for any pair of vertices l and l', there exists a path that starts in l and ends in l'. Let $\mathcal{L}^+ \subseteq \mathcal{V}, \mathcal{L}^+ \neq \emptyset$ denote the set of nodes that the aggregator is able to directly communicate with.

The processor of each DER i maintains two values y_i and z_i, which we refer to as internal states, and updates them (independently of each other) to be, respectively, a linear combination of DER i's own previous internal states and the previous internal states of all nodes that can possibly transmit information to node i (including itself). In particular, for all $k \geq 0$, each node i updates its two internal states as follows:

$$y_i[k+1] = \sum_{j \in \mathcal{N}_i^-} \frac{1}{\mathcal{D}_j^+} y_j[k], \qquad (4)$$

$$z_i[k+1] = \sum_{j \in \mathcal{N}_i^-} \frac{1}{\mathcal{D}_j^+} z_j[k], \qquad (5)$$

where $\mathcal{N}_i^- = \{j \in \mathcal{V} : (i, j) \in \mathcal{E}\}$, i.e., all nodes that can possibly transmit information to node i (including itself); and $\mathcal{D}_i^+$ is the out-degree of node i, i.e., the number of nodes to which node i can possibly transmit information (including itself). The initial conditions in (4) are set to $y_i[0] = X/m - \underline{x}_i$ if $i \in \mathcal{L}^+$, and $y_i[0] = -\underline{x}_i$ otherwise and the initial conditions in (5) are set to $z_i[0] = \overline{x}_i - \underline{x}_i$. Then, as shown in Domínguez-García and Hadjicostis (2011), as long as $\sum_{l=1}^n \overline{x}_l \leq X \leq \sum_{l=1}^n \overline{x}_l$, each DER i can asymptotically calculate its contribution as

$$x_i = \underline{x}_i + \gamma(\overline{x}_i - \underline{x}_i) \qquad (6)$$

where for all i

$$\lim_{k \to \infty} \frac{y_i[k]}{z_i[k]} = \frac{X - \sum_{l=1}^n \underline{x}_l}{\sum_{l=1}^n (\overline{x}_l - \underline{x}_l)} := \gamma. \qquad (7)$$

It is important to note that the algorithm in (4)–(7) also serves as a primitive for the algorithm proposed in Domínguez-García et al. (2012a), which solves the problem in (1) when the cost function is quadratic. Also, the algorithm in (4)–(7) is not resilient to packet-dropping communication links or imperfect synchronization among the DERs, which makes it difficult to implement in practice; however, there are robustified variants of this algorithm that address these issues Domínguez-García et al. (2012b) and have been demonstrated to work in practice (Domínguez-García et al. 2012a).

Credit Risk Modeling

Tomasz R. Bielecki
Department of Applied Mathematics, Illinois Institute of Technology, Chicago, IL, USA

Abstract

Modeling of credit risk is concerned with constructing and studying formal models of time evolution of credit ratings (credit migrations) in a pool of credit names, and with studying various properties of such models. In particular, this involves modeling and studying default times and their functionals.

Keywords

Credit risk; Credit migrations; Default time; Markov copulae

Introduction

Modeling of credit risk is concerned with constructing and studying formal models of time evolution of credit ratings (credit migrations) in a pool of N credit names (obligors), and with studying various properties of such models. In particular, this involves modeling and studying default times and their functionals. In many ways, modeling techniques used in credit risk are similar to modeling techniques used in reliability theory. Here, we focus on modeling in continuous time.

Models of credit risk are used for the purpose of valuation and hedging of credit derivatives, for valuation and hedging of counter-party risk, for assessment of systemic risk in an economy, or for constructing optimal trading strategies involving credit-sensitive financial instruments, among other uses.

Evolution of credit ratings for a single obligor, labeled as i, where $i \in \{1, \ldots, N\}$, can be

modeled in many possible ways. One popular possibility is to model credit migrations in terms of a jump process, say $C^i = (C^i_t)_{t \geq 0}$, taking values in a finite set, say $\mathcal{K}^i := \{0, 1, 2, \ldots, K^i - 1, K^i\}$, representing credit ratings assigned to obligor i. Typically, the rating state K^i represents the state of default of the i-th obligor, and typically it is assumed that process C^i is absorbed at state K^i.

Frequently, the case when $K^i = 1$, that is $\mathcal{K}^i := \{0, 1\}$, is considered. In this case, one is only concerned with jump from the pre-default state 0 to the default state 1, which is usually assumed to be absorbing – the assumption made here as well. It is assumed that process C^i starts from state 0. The (random) time of jump of process C^i from state 0 to state 1 is called the default time, and is denoted as τ^i. Process C^i is now the same as the indicator process of τ^i, which is denoted as H^i and defined as $H^i_t = \mathbb{1}_{\{\tau^i \leq t\}}$, for $t \geq 0$. Consequently, modeling of the process C^i is equivalent to modeling of the default time τ^i.

The ultimate goal of credit risk modeling is to provide a feasible mathematical and computational methodology for modeling the evolution of the multivariate credit migration process $\mathbf{C} := (C^1, \ldots, C^N)$, so that relevant functionals of such processes can be computed efficiently. The simplest example of such functional is $P(\mathbf{C}_{t_j} \in A_j, j = 1, 2, \ldots, J | \mathcal{G}_s)$, representing the conditional probability, given the information $\mathcal{G}_s$ at time $s \geq 0$, that process $\mathbf{C}$ takes values in the set A_j at time $t_j \geq 0$, $j = 1, 2, \ldots, J$. In particular, in case of modeling of the default times τ^i, $i = 1, 2, \ldots, N$, one is concerned with computing conditional survival probabilities $P(\tau^1 > t_1, \ldots, \tau^N > t_N | \mathcal{G}_s)$, which are the same as probabilities $P(H^i_{t_i} = 0, i = 1, 2, \ldots, N | \mathcal{G}_s)$.

Based on that, one can compute more complicated functionals, that naturally occur in the context of valuation and hedging of credit risk–sensitive financial instruments, such as corporate (defaultable) bonds, credit default swaps, credit spread options, collateralized bond obligations, and asset-based securities, for example.

Modeling of Single Default Time Using Conditional Density

Traditionally, there were two main approaches to modeling default times: the structural approach and the reduced approach, also known as the hazard process approach. The main features of both these approaches are presented in Bielecki and Rutkowski (2004).

We focus here on modeling a single default time, denoted as τ, using the so-called conditional density approach of El Karoui et al. (2010). This approach allows for extension of results that can be derived using reduced approach.

The default time τ is a strictly positive random variable defined on the underlying probability space $(\Omega, \mathcal{F}, P)$, which is endowed with a reference filtration, say $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$, representing flow of all (relevant) market information available in the model, not including information about occurrence of τ. The information about occurrence of τ is carried by the (right continuous) filtration $\mathbb{H}$ generated by the indicator process $H := (H_t = \mathbb{1}_{\tau \leq t})_{t \geq 0}$. The full information in the model is represented by filtration $\mathbb{G} := \mathbb{F} \vee \mathbb{H}$.

It is postulated that

$$P(\tau \in d\theta | \mathcal{F}_t) = \alpha_t(\theta)d\theta,$$

for some random field $\alpha.(\cdot)$, such that $\alpha_t(\cdot)$ is $\mathcal{F}_t \otimes \mathcal{B}(\mathbb{R}_+)$ measurable for each t. The family $\alpha_t(\cdot)$ is called $\mathcal{F}_t$-conditional density of τ. In particular, $P(\tau > \theta) = \int_\theta^\infty \alpha_0(u) \, du$. The following survival processes are associated with τ,

- $S_t(\theta) := P(\tau > \theta | \mathcal{F}_t) = \int_\theta^\infty \alpha_t(u) \, du$, which is an $\mathbb{F}$-martingale,
- $S_t := S_t(t) = P(\tau > t | \mathcal{F}_t)$, which is an $\mathbb{F}$-supermartingale (Azéma supermartingale).

In particular, $S_0(\theta) = P(\tau > \theta) = \int_\theta^\infty \alpha_0(u) \, du$, and $S_t(0) = S_0 = 1$.

As an example of computations that can be done using the conditional density approach we give the following result, in which notation "bd" and "ad" stand for `before default` and `at-or-after default`, respectively.

Theorem 1 *Let $Y_T(\tau)$ be a $\mathcal{F}_T \vee \sigma(\tau)$ measurable and bounded random variable. Then*

$$E(Y_T(\tau)|\mathcal{F}_t) = Y_t^{\mathrm{bd}}\mathbb{1}_{t < \tau} + Y_t^{\mathrm{ad}}(T, \tau)\mathbb{1}_{t \geq \tau},$$

where

$$Y_t^{\mathrm{bd}} = \frac{\int_t^\infty Y_T(\theta)\alpha_t(\theta)d\theta}{S_t}\mathbb{1}_{S_t > 0},$$

and

$$Y_t^{\mathrm{ad}}(T, \theta) = \frac{E(Y_T(\theta)\alpha_T(\theta)|\mathcal{F}_t)}{\alpha_t(\theta)}\mathbb{1}_{\alpha_t(\theta) > 0}.$$

There is an interesting connection between the conditional density process and the so-called default intensity processes, which are ones of the main objects used in the reduced approach. This connection starts with the following result,

Theorem 2 *(i) The Doob-Meyer (additive) decomposition of the survival process S is given as*

$$S_t = 1 + M_t^{\mathbb{F}} - \int_0^t \alpha_u(u)du,$$

where $M_t^{\mathbb{F}} = -\int_0^t (\alpha_t(u) - \alpha_u(u))du = E(\int_0^\infty \alpha_u(u)du|\mathcal{F}_t) - 1$.

(ii) Let $\xi := \inf\{t \geq 0 : S_{t-} = 0\}$. Define $\lambda_t^{\mathbb{F}} = \frac{\alpha_t(t)}{S_t}$ for $t < \xi$ and $\lambda_t^{\mathbb{F}} = \lambda_\xi^{\mathbb{F}}$ for $t \geq \xi$. Then, the multiplicative decomposition of S is given as

$$S_t = L_t^{\mathbb{F}} e^{-\int_0^t \lambda_u^{\mathbb{F}}du},$$

where

$$dL_t^{\mathbb{F}} = e^{\int_0^t \lambda_u^{\mathbb{F}}du}dM_t^{\mathbb{F}}, \quad L_0^{\mathbb{F}} = 1.$$

The process $\lambda^{\mathbb{F}}$ is called the $\mathbb{F}$ intensity of τ.

The $\mathbb{G}$-compensator of τ is the $\mathbb{G}$-predictable increasing process $\Lambda^{\mathbb{G}}$ such that the process

$$M_t^{\mathbb{G}} = H_t - \Lambda_t^{\mathbb{G}}$$

is a $\mathbb{G}$-martingale. If $\Lambda^{\mathbb{G}}$ is absolutely continuous, the $\mathbb{G}$-adapted process $\lambda^{\mathbb{G}}$ such that

$$\Lambda_t^{\mathbb{G}} = \int_0^t \lambda_u^{\mathbb{G}}du$$

is called the $\mathbb{G}$-intensity of τ. The $\mathbb{G}$-compensator is stopped at τ, i.e., $\Lambda_t^{\mathbb{G}} = \Lambda_{t \wedge \tau}^{\mathbb{G}}$. Hence, $\lambda_t^{\mathbb{G}} = 0$ when $t > \tau$. In particular, we have

$$\lambda_t^{\mathbb{G}} = \mathbb{1}_{t < \tau}\lambda_t^{\mathbb{F}} = (1 - H_t)\lambda_t^{\mathbb{F}}.$$

The conditional density process and the $\mathbb{G}$-intensity of τ are related as follows: For any $t < \xi$ and $\theta \geq t$ we have

$$\alpha_t(\theta) = E(\lambda_\theta^{\mathbb{G}}|\mathcal{F}_t).$$

Example 1 This is a structural-model-like example
- Suppose $\mathbb{F} = \mathbb{F}^X$ is a filtration of a default driver process, say X, and Θ is the default barrier assumed to be independent of X. Denote $G(t) = P(\Theta > t)$.
- Define

$$\tau := \inf\{t \geq 0 : \Gamma_t \geq \Theta\},$$

with $\Gamma_t := \sup_{s \leq t} X_s$. We then have $S_t(\theta) = G(\Gamma_\theta)$ if $\theta \leq t$ and $S_t(\theta) = E(G(\Gamma_\theta)|\mathcal{F}_t^X)$ if $\theta > t$
- Assume that $F = 1 - G$ and Γ are absolutely continuous w.r.t. Lebesgue measure, with respective densities f and γ. We then have

$$\alpha_t(\theta) = f(\Gamma_\theta)\gamma_\theta = \alpha_\theta, \, t \geq \theta,$$

and $\mathbb{F}^X$ intensity of τ is

$$\lambda_t = \frac{\alpha_t(t)}{G(\Gamma_t)} = \frac{\alpha_t(t)}{S_t}.$$

- In particular, if Θ is a unit exponential r.v., that is, if $G(t) = e^{-t}$ for $t \geq 0$, then we have that $\lambda_t = \gamma_t = \frac{\alpha_t(t)}{S_t}$.

Example 2 This is a reduced-form-like example.

- Suppose S is a strictly positive process. Then, the $\mathbb{F}$-hazard process of τ is denoted by $\Gamma^{\mathbb{F}}$ and is given as

$$\Gamma_t^{\mathbb{F}} = -\ln S_t, \quad t \geq 0.$$

In other words,

$$S_t = e^{-\Gamma_t^{\mathbb{F}}}, \quad t \geq 0.$$

- In particular, if $\Gamma^{\mathbb{F}}$ is absolutely continuous, that is, $\Gamma_t^{\mathbb{F}} = \int_0^t \gamma_u^{\mathbb{F}} \, du$ then

$$S_t = e^{-\int_0^t \gamma_u^{\mathbb{F}} \, du}, \quad t \geq 0 \quad \text{and}$$

$$\alpha_t(\theta) = \gamma_\theta^{\mathbb{F}} S_\theta, \; t \geq \theta.$$

Modeling Evolution of Credit Ratings Using Markov Copulae

The key goal in modeling of the joint migration process $\mathbf{C}$ is that the distributional laws of the individual migration components C^i, $i \in \{1, \ldots, N\}$, agree with given (predetermined) laws. The reason for this is that the marginal laws of $\mathbf{C}$, that is, the laws of C^i, $i \in \{1, \ldots, N\}$, can be calibrated from market quotes for prices of individual (as opposed to basket) credit derivatives, such as the credit default swaps, and thus, the marginals of $\mathbf{C}$ should have laws agreeing with the market data.

One way of achieving this goal is to model $\mathbf{C}$ as a Markov chain satisfying the so-called Markov copula property. For brevity we present here the simplest such model, in which the reference filtration $\mathbb{F}$ is trivial, assuming additionally, but without loss of generality, that $N = 2$ and that $\mathcal{K}^1 = \mathcal{K}^2 = \mathcal{K} := \{0, 1, \ldots, K\}$.

Here we focus on the case of the so-called strong Markov copula property, which is reflected in Theorem 3.

Let us consider two Markov chains Z^1 and Z^2 on $(\Omega, \mathcal{F}, P)$, taking values in a finite state space $\mathcal{K}$, and with the infinitesimal generators $A^1 := [a_{ij}^1]$ and $A^2 := [a_{hk}^2]$, respectively.

Consider the system of linear algebraic equations in unknowns $a_{ih,jk}^{\mathbf{C}}$,

$$\sum_{k \in \mathcal{K}} a_{ih,jk}^{\mathbf{C}} = a_{ij}^1, \quad \forall i, j, h \in \mathcal{K}, \; i \neq j, \quad (1)$$

$$\sum_{j \in \mathcal{K}} a_{ih,jk}^{\mathbf{C}} = a_{hk}^2, \quad \forall i, h, k \in \mathcal{K}, \; h \neq k, \quad (2)$$

It can be shown that this system admits at least one positive solution.

Theorem 3 *Consider an arbitrary positive solution of the system* (1)–(2)*. Then the matrix* $A^{\mathbf{C}} = [a_{ih,jk}^X]_{i,h,j,k \in \mathcal{K}}$ *(where diagonal elements are defined appropriately) satisfies the conditions for a generator matrix of a bivariate time-homogeneous Markov chain, say* $\mathbf{C} = (C^1, C^2)$*, whose components are Markov chains in the filtration of* $\mathbf{C}$ *and with the same laws as* Z^1 *and* Z^2*.*

Consequently, the system (1)–(2) serves as a Markov copula between the Markovian margins C^1, C^2 and the bivariate Markov chain $\mathbf{C}$.

Note that the system (1)–(2) can contain more unknowns than the number of equations, therefore being underdetermined, which is a crucial feature for ability of calibration of the joint migration process $\mathbf{C}$ to marginal market data.

Example 3 This example illustrates modeling joint defaults using strong Markov copula theory.

Let us consider two processes, Z^1 and Z^2, that are time-homogeneous Markov chains, each taking values in the state space $\{0, 1\}$, with respective generators

$$A^1 = \begin{matrix} \\ 0 \\ 1 \end{matrix} \begin{matrix} 0 & \quad 1 \\ \begin{pmatrix} -(a+c) & a+c \\ 0 & 0 \end{pmatrix} \end{matrix} \quad (3)$$

and

$$A^2 = \begin{matrix} \\ 0 \\ 1 \end{matrix} \begin{matrix} 0 & \quad 1 \\ \begin{pmatrix} -(b+c) & b+c \\ 0 & 0 \end{pmatrix} \end{matrix}, \quad (4)$$

for $a, b, c \geq 0$.

The off-diagonal elements of the matrix $A^{\mathbf{C}}$ below satisfy the system (1)–(2),

$$A^{\mathbf{C}} = \begin{array}{c} \\ (0,0) \\ (0,1) \\ (1,0) \\ (1,1) \end{array} \begin{array}{cccc} (0,0) & (0,1) & (1,0) & (1,1) \\ \begin{pmatrix} -(a+b+c) & b & a & c \\ 0 & -(a+c) & 0 & a+c \\ 0 & 0 & -(b+c) & b+c \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array}. \tag{5}$$

Thus, matrix $A^{\mathbf{C}}$ generates a Markovian joint migration process $\mathbf{C} = (C^1, C^2)$, whose components C^1 and C^2 model individual default with prescribed default intensities $a + c$ and $b + c$, respectively.

For more information about Markov copulae and about their applications in credit risk we, refer to Bielecki et al. (2013).

Summary and Future Directions

The future directions in development and applications of credit risk models are comprehensively laid out in the recent volume Bielecki et al. (2011). One additional future direction is modeling of systemic risk.

Data Association

Yaakov Bar-Shalom and Richard W. Osborne
University of Connecticut, Storrs, CT, USA

Abstract

In tracking applications, following the signal detection process that yields measurements, there is a procedure that *selects* the measurement(s) to be incorporated into the state estimator – this is called **data association (DA)**. In multitarget-multisensor tracking systems, there are generally three classes of data association: specifically, **measurement-to-track association (M2TA)**, **track-to-track association (T2TA)**, and **measurement-to-measurement association (M2MA)**. M2TA is the process of associating each measurement from a list (originating from one or more sensors) to a new or existing track. T2TA is the process of associating multiple existing tracks (from multiple sensors or from different periods in time), generally with the intent of fusing them afterward. M2MA is the process of associating measurements from different sensors in order to form "composite measurements" and/or do track initialization. The processes of M2TA and T2TA will be discussed in more detail here, while details on M2MA can be found in Bar-Shalom et al. (2011).

Keywords

Clutter; Measurement origin uncertainty; Measurement validation; Persistent interference; Tracking

Introduction

In a radar the "return" from the target of interest is sought within a time interval determined by the anticipated range of the target when it reflects the energy transmitted by the radar: a "range gate" is set up and the detection(s) within this gate can be *associated* with the target of interest.

In general the measurements have a higher dimension:

- Range, azimuth (bearing), elevation, or direction sines for radar, possibly also range rate
- Bearing and frequency (when the signal is narrow band) or time difference of arrival and frequency difference in passive sonar
- Two line-of-sight angles or direction sines for optical or passive electromagnetic sensors

Then a *multidimensional* **gate** is set up for detecting the signal from the target. This is done to avoid searching for the signal from the target of interest in the entire measurement space. A measurement in the gate, while not guaranteed to have originated from the target the gate pertains to, is a *valid association candidate* – thus, the name **validation region** or **association region**. If there

is more than one detection (measurement) in the gate, this leads to an **association uncertainty**.

In the discussion to follow, it will be assumed that one has **point measurements** rather than distributed over several **resolution cells** of the sensor as in the case of an **extended target**.

Similar validation has to be carried out in T2TA.

Validation Region

In view of the variety of variables that can be measured, a generic gating (or validation or association) procedure for continuous-valued measurements is discussed.

Consider a target that is in track, i.e., its filter has been initialized. Then, according to Sect. 5.2.3 of Bar-Shalom et al. (2001), one has the predicted value (mean) of the measurement $\hat{z}(k+1|k)$ and the associated covariance $S(k+1)$.

Assumption. The true measurement conditioned on the past is **normally (Gaussian) distributed** (The notation $\mathcal{N}(x; \mu, S)$ stands for the normal (Gaussian) pdf with the argument (vector) random variable x, mean μ, and covariance matrix S. The reason for the use of the designation "normal" is to distinguish this omnipresent pdf from all the others (abnormal).) with its **probability density function (pdf)** given by

$$p[z(k+1)|Z^k] = \mathcal{N}[z(k+1); \hat{z}(k+1|k),$$
$$S(k+1)] \quad (1)$$

where $S(k+1)$ is the **innovation (residual) covariance** matrix and z is the true measurement.

Then the true measurement will be in the following region:

$$\mathcal{V}(k+1, \gamma) = \{z : d^2 \leq \gamma\} \quad (2)$$

with probability determined by the **gate threshold** γ and

$$d^2 \triangleq [z - \hat{z}(k+1|k)]' S(k+1)^{-1} [z - \hat{z}(k+1|k)] \quad (3)$$

This distance metric, d^2, is referred to in the literature as the **normalized innovation squared (NIS)**, **statistical distance squared**, **Mahalanobis distance**, or **chi-square distance**.

The region defined by (2) is called the **gate** or **validation region** (hence, the notation $\mathcal{V}$) or **association region**. It is also known as the **ellipse (or ellipsoid) of probability concentration** – the region of *minimum volume* that contains a given probability mass under the Gaussian assumption. The semiaxes of the ellipsoid (2) are the square roots of the eigenvalues of γS. The threshold γ is obtained from tables of the chi-square distribution since the quadratic form (3) that defines the validation region in (2) is chi-square distributed with number of degrees of freedom equal to the dimension n_z of the measurement.

Table 1 gives the **gate probability** (The notation $P\{\cdot\}$ is used to denote the probability of event $\{\cdot\}$.)

$$P_G \triangleq P\{z(k+1) \in \mathcal{V}(k+1, \gamma)\} \quad (4)$$

or the "probability that the (true) measurement will fall in the gate" for various values γ and dimensions n_z of the measurement. The square root $g = \sqrt{\gamma}$ is sometimes referred to as the "number of sigmas" (standard deviations) of the gate. This, however, does not fully define the probability mass in the gate as can be seen from Table 1.

Remark 1 It should be pointed out that thresholding in a detector is also a form of gating – only a signal above a certain intensity level (at the end of the signal processing chain) is accepted as a detection and then one has a measurement. In this case the "gate" is the interval $[\tau, \infty]$ in the signal intensity space, where τ is the detection threshold.

A Single Target in Clutter

The validation procedure limits the region in the measurement space where the information processor will "look" to find the measurement from the target of interest. In spite of this, it can happen that *more than one detection*, i.e., several measurements, will be found in the validation region.

Data Association, Table 1 Gate thresholds and the probability mass P_G in the gate

	γ	1	4	6.6	9	9.2	11.4	16	25
	g	1	2	2.57	3	3.03	3.38	4	5
n_z									
1		0.683	0.954	0.99	0.997			0.99994	1
2		0.393	0.865		0.989	0.99		0.9997	1
3		0.199	0.739		0.971		0.99	0.9989	0.99998

Measurements *outside the validation region* can be ignored: they are "too far" and thus very unlikely to have originated from the target of interest. This holds if the gate probability is close to unity and *the model used to obtain the gate is correct*.

The problem of tracking a single target in clutter considers the situation where there are possibly several measurements in the validation region (gate) of a target. The set of **validated measurements** consists of:

- The correct measurement (if detected and it fell in the gate)
- The undesirable measurements: clutter or false alarm originated

In practice detections are obtained by thresholding the signal received by the sensor after processing it. This is the simplest (binary) way of using a target **feature** – its intensity. More sophisticated ways of using such feature information can be found in Bar-Shalom et al. (2011).

It is assumed that the measurement contains all the information that could be used to discard the undesirable measurements. Therefore, any measurement that has been validated could have originated from the target of interest.

A situation with a single-target track and several validated measurements is depicted in Fig. 1. The (two-dimensional) validation region is an ellipse centered at the predicted measurement $\hat{z}^1$. The parameters of the ellipse are determined by the covariance matrix S of the innovation, which is assumed to be Gaussian.

All the measurements in the validation region can be said to be *not too unlikely* to have originated from the target of interest, even though only one is assumed to be the true one.

The implication of the assumption that there is a single target is that the *undesirable measurements constitute a random interference*.
Data Association, Fig. 1 Several measurements in the validation region of a single track

The common mathematical model for such **false measurements** is that they are:

- Uniformly spatially distributed
- Independent across time

This corresponds to what is known as **residual clutter** – the constant clutter, if any, is assumed to have been removed.

Multiple Targets in Clutter

The situation where there are several target tracks in the same neighborhood as well as clutter (or false alarms) is more complicated. Figure 2 illustrates such a case for a given time, with the predicted measurements for the two targets considered denoted as $\hat{z}^1$ and $\hat{z}^2$. In this figure the following measurement origins are possible:

- z_1 from target 1 or clutter
- z_2 from either target 1 or target 2 or clutter
- z_3 and z_4 from target 2 or clutter

However, if z_2 originated from target 2, then it is quite likely that z_1 originated from target 1. This illustrates the *interdependence of the associations* in a situation where a **persistent interference** (neighboring target) is present in addition to random interference (clutter).
Data Association, Fig. 2 Two tracks with a measurement in the intersection of their validation regions

Up to this point, it was assumed that a measurement could have originated from *one of the targets* or from *clutter*. However, in view of the fact that any signal processing system has an inherent **finite resolution** capability, an additional possibility has to be considered:

   z_2 could be the result of the **merging** of the detections from the two targets – it is an **unresolved measurement**.

This constitutes a fourth origin hypothesis for a measurement that lies in the intersection of two validation regions. Most tracking algorithms ignore the possibility that a measurement is an unresolved one.

This illustrates only the difficulty of association of measurements to tracks *at one point in time*. The full problem, as will be discussed later, consists of associating measurements *across time*.

Approaches to Tracking and Data Association

The problem of **tracking and data association** is a **hybrid** problem because it is characterized by:

(1) Continuous uncertainties – state estimation in the presence of continuous noises
(2) Discrete uncertainties – which measurement(s) should be used in the estimation process

Assuming the goal is to obtain the MMSE estimate of the target state – its conditional mean – one can distinguish the following approaches.

Pure MMSE Approach
The **Pure MMSE Approach** to tracking and data association is obtained using the smoothing property of expectations (see, e.g., Bar-Shalom et al. 2001, Sect. 1.4.12), as follows:

$$\hat{x}^{\text{MMSE}} = E[x|Z] = E\{E[x|A, Z]|Z\}$$
$$= \sum_{A_i \in \mathcal{A}} E[x|A_i, Z]P\{A_i|Z\} \qquad (5)$$

where A is an association event (assuming a Bayesian model, with prior probabilities from which one can calculate posterior probabilities), and the summation is over all events A_i in the set $\mathcal{A}$ of mutually exclusive and exhaustive association events.

The above, which requires the evaluation of all the conditional (posterior) probabilities $P\{A_i|Z\}$, is a direct consequence of the **total probability theorem** (see, e.g., Bar-Shalom et al. 2001, Sect. 1.4.10), which yields the conditional pdf of the state as the following mixture

$$p(x|Z) = \sum_{A_i \in \mathcal{A}} p(x|A_i, Z)P\{A_i|Z\} \qquad (6)$$

In the linear-Gaussian case the above becomes a **Gaussian mixture**. Algorithms that fall in this category are PDAF and JPDAF, see Bar-Shalom et al. (2011).

MMSE-MAP Approach
The **MMSE-MAP Approach**, instead of enumerating and summing over all the association events, selects the one with highest posterior probability, namely,

$$A^{\text{MAP}} = \arg\max_i P\{A_i|Z\} \qquad (7)$$

and then

$$\hat{x}^{\text{MMSE-MAP}} = E[x|A^{\text{MAP}}, Z] \qquad (8)$$

The HOMHT as proposed by Reid (1979) falls in this category, see Bar-Shalom et al. (2011).

MMSE-ML Approach
The **MMSE-ML Approach** does not assume priors for the association events and relies on the maximum likelihood approach to select the event, that is,

$$A^{\text{ML}} = \arg\max_i p\{Z|A_i|\} \qquad (9)$$

and then

$$\hat{x}^{\text{MMSE-ML}} = E[x|A^{\text{ML}}, Z] \qquad (10)$$

The TOMHT falls into this category and S-D assignment (or MDA) is an implementation of this, see Bar-Shalom et al. (2011).

Heuristic Approaches
There are numerous simpler/heuristic approaches. The most common one relies on the distance metric (3) and makes the selection of which measurement is associated with which track based on the "nearest neighbor" rule. The same criterion can be used in a global cost function.

Remarks
It should be noted that the MMSE-MAP estimate (8) and the MMSE-ML estimate (10) are obtained assuming that the selected association is *correct* – a **hard decision**. This hard decision is sometimes correct, sometimes wrong. On the other hand, the pure MMSE estimate (5) yields a **soft decision** – it averages over all the possibilities. This soft decision is never totally correct, never totally wrong.

The uncertainties (covariances) associated with the MMSE-MAP and MMSE-ML estimates might be optimistic in view of the above observation. The uncertainty associated with the pure MMSE estimate will be *increased* (realistically) in view of the fact that it includes the data association uncertainty.

Estimation and Data Association in Nonlinear Stochastic Systems

The Model
Consider the discrete time stochastic system

$$\mathbf{x}(k + 1) = f[k, \mathbf{x}(k), \mathbf{u}(k), \mathbf{v}(k)] \qquad (11)$$

where $\mathbf{x} \in \mathcal{R}^n$ is the stacked state vector of the targets under consideration, $\mathbf{u}(k)$ is a known input (included here for the sake of generality), and $\mathbf{v}(k)$ is the process noise with a known pdf. The measurements at time $k + 1$ are described by the stacked vector

$$\mathbf{z}(k+1) = h[k+1, \mathbf{x}(k+1), A(k+1), \mathbf{w}(k+1)] \qquad (12)$$

where $A(k + 1)$ is the data association event at $k + 1$ that specifies (i) which measurement component originated from which components of $\mathbf{x}(k + 1)$, namely, from which target, and (ii) which measurements are false, that is, originated from the clutter process. The vector $\mathbf{w}(k)$ is the observation noise, consisting of the error in the true measurement and the false measurements. The pdf of the false measurements and the probability mass function (pmf) of their number are also assumed to be known.

The noise sequences and false measurements are assumed to be white with known pdf and mutually independent. The initial state is assumed to have a known pdf and to be independent of the noises. Additional assumptions are given below for the optimal estimator, which evaluates the pdf of the state conditioned on the observations.

The optimal state estimator in the presence of data association uncertainty consists of the computation of the conditional pdf of the state $\mathbf{x}(k)$ given all the information available at time k, namely, the prior information about the initial state, the intervening inputs, and the sets of measurements through time k. The conditions under which the optimal state estimator consists of the computation of this pdf are presented in detail.

The Optimal Estimator for the Pure MMSE Approach

The **information set** available at k is

$$I^k = \{Z^k, U^{k-1}\} \tag{13}$$

where

$$Z^k \triangleq \{\mathbf{z}(j)\}_{j=1}^k \tag{14}$$

is the cumulative set of observations through time k, which subsumes the initial information Z^0, and U^{k-1} is the set of known inputs prior to time k.

For a stochastic system, an **information state** (Striebel 1965) is a function of the available information set that summarizes the past of the system in a probabilistic sense.

It can be shown that the conditional pdf of the state

$$p_k \triangleq p[\mathbf{x}(k)|I^k] \tag{15}$$

is an information state if (i) the two noise sequences (process and measurement) are white and mutually independent and (ii) the target detection and clutter/false measurement processes are white. Once the conditional pdf (15) is available, the **pure MMSE estimator**, i.e., the conditional mean, as well as the conditional variance, or covariance matrix, can be obtained.

The optimal estimator, which consists of the recursive functional relationship between the information states p_{k+1} and p_k, is given by

$$p_{k+1} = \psi[k+1, p_k, \mathbf{z}(k+1), \mathbf{u}(k)] \tag{16}$$

where

$$
\begin{aligned}
&\psi[k+1, p_k, \mathbf{z}(k+1), \mathbf{u}(k)] \\
&= \frac{1}{c} \sum_{i=1}^{M(k+1)} p[\mathbf{z}(k+1)|\mathbf{x}(k+1), A_i(k+1)] \\
&\quad \cdot \int p[\mathbf{x}(k+1)|\mathbf{x}(k), \mathbf{u}(k)] p_k \, d\mathbf{x}(k) \\
&\quad P\{A_i(k+1)\}
\end{aligned}
\tag{17}
$$

is the transformation that maps p_k into p_{k+1}; the integration in (17) is over the range of $\mathbf{x}(k)$ and c is the normalization constant.

The recursion (17) shows that the optimal MMSE estimator in the presence of data association uncertainty has the following properties:

P1. The pdf p_{k+1} is a weighted sum of pdfs, conditioned on the current time association events $A_i(k+1)$, $i = 1, \ldots, M(k+1)$, where $M(k+1)$ is the number of mutually exclusive and exhaustive association events at time $k+1$.

P2. If the exact previous pdf, which is the sufficient statistic, is available, then only the most recent association event probabilities are needed at each time.

However, the number of terms of the mixture in the right-hand side of (17) is, by time $k+1$, given by the product

$$M^{k+1} = \prod_{i=1}^{k+1} M(i) \tag{18}$$

which amounts to an exponential increase in time. This increase is similar to the increase in the number of the branches of the MHT hypothesis tree.

A detailed derivation of the recursion for the optimal estimator can be found in Bar-Shalom et al. (2011).

Track-to-Track Association

In addition to **measurement-to-track association (M2TA)**, an additional class of data association is **track-to-track association (T2TA)**. Following T2TA, **track-to-track fusion (T2TF)** may be performed to (hopefully) improve the overall tracking accuracy. For more details on track fusion, see Bar-Shalom et al. (2011).

It is desired first to test the hypothesis that two tracks pertain to the same target. The optimal test would require using the entire data base (the sequences of measurements that form the tracks) through the present time k and is not practical. In view of this, the test to be presented is based only on the most recent estimates from the tracks. The test based on the state estimates within a time window is discussed in Tian and Bar-Shalom (2009).

Association of Tracks with Independent Errors

Let $\hat{x}^i(k)$ be the estimated state of a target by sensor i with its own information processor. Assume that one has an estimate $\hat{x}^j(k)$ from sensor j, corresponding to the same time. Both can be current estimates or one can be a prediction as long as they pertain to the same time (the second time argument has been omitted for simplicity).

The corresponding covariances are denoted as $P^m(k), m = i, j$. The state estimation errors at different sensors (local trackers),

$$\tilde{x}^i(k) = x^i(k) - \hat{x}^i(k) \qquad (19)$$

$$\tilde{x}^j(k) = x^j(k) - \hat{x}^j(k) \qquad (20)$$

where x^i and x^j are the corresponding true states, are assumed to be *independent*. This is the **state estimation error independence assumption**.

Remark 2 As shown in the sequel, for *independent sensors*, the state estimation errors for the same target are *dependent* in the *presence of process noise*.

Denote the difference of the two estimates as

$$\hat{\Delta}^{ij}(k) = \hat{x}^i(k) - \hat{x}^j(k) \qquad (21)$$

This is the estimate of the difference of the true states

$$\Delta^{ij}(k) = x^i(k) - x^j(k) \qquad (22)$$

The **same target hypothesis** is that the true states are equal,

$$H_0: \qquad \Delta^{ij}(k) = 0 \qquad (23)$$

while the *different target* alternative is

$$H_1: \qquad \Delta^{ij}(k) \neq 0 \qquad (24)$$

While (21) is the appropriate statistic to test whether (22) is zero or not, the rigorous proof of this fact is presented in Bar-Shalom et al. (2011).

The error in the difference between the state estimates

$$\tilde{\Delta}^{ij}(k) = \Delta^{ij}(k) - \hat{\Delta}^{ij}(k) \qquad (25)$$

is zero mean and has covariance

$$T^{ij}(k) \triangleq E\{\tilde{\Delta}^{ij}(k)\tilde{\Delta}^{ij}(k)'\}$$
$$= E\{[\tilde{x}^i(k) - \tilde{x}^j(k)][\tilde{x}^i(k) - \tilde{x}^j(k)]'\} \qquad (26)$$

given, under the **error independence assumption**, by

$$T^{ij}(k) = P^i(k) + P^j(k) \qquad (27)$$

Assuming the estimation errors to be Gaussian, the test of H_0 vs. H_1 – the **T2TA** test – is

Accept H_0 if

$$D \triangleq \hat{\Delta}^{ij}(k)'[T^{ij}(k)]^{-1}\hat{\Delta}^{ij}(k) \leq D_\alpha \quad (28)$$

The threshold D_α is such that

$$P\{D > D_\alpha | H_0\} = \alpha \qquad (29)$$

where, e.g., $\alpha = 0.01$. From the Gaussian assumption, the threshold is the $1 - \alpha$ point of the **chi-square distribution** with n_z degrees of freedom (Bar-Shalom et al. 2001)

$$D_\alpha = \chi^2_{n_z}(1 - \alpha) \qquad (30)$$

Association of Tracks with Dependent Errors

In the previous section, the association testing was done under the assumption that the estimation errors in these tracks are independent. However, as shown in Bar-Shalom et al. (2011), *whenever there is process noise* (or, in general, motion uncertainty), the track errors based on data from *independent sensors* are *dependent*.

The *dependence* between the estimation errors $\tilde{x}^i(k|k)$ and $\tilde{x}^j(k|k)$ from the two tracks arises from the *common process noise* which contributes to both errors. This is due to the fact that there is a common motion equation for both trackers.

The testing of the hypothesis that the two tracks under consideration originated from the same target is done in the same manner as before,

except for the following modification to account for the *dependence* of their state estimation errors.

The covariance associated with the difference of the estimates

$$\hat{\Delta}^{ij}(k) = \hat{x}^i(k|k) - \hat{x}^j(k|k) \qquad (31)$$

is, accounting for the dependence,

$$T^{ij}(k) \triangleq E\{\tilde{\Delta}^{ij}(k)\tilde{\Delta}^{ij}(k)'\}$$
$$= E\{[\tilde{x}^i(k|k) - \tilde{x}^j(k|k)][\tilde{x}^i(k|k)$$
$$- \tilde{x}^j(k|k)]'\} \qquad (32)$$

and, with the known cross-covariance P^{ij}, is given by the expression

$$T^{ij}(k) = P^i(k|k) + P^j(k|k)$$
$$- P^{ij}(k|k) - P^{ji}(k|k) \qquad (33)$$

Note the difference between the above and (27).

Effect of the Dependence

The effect of the dependence between the estimation errors is to *reduce* the covariance of the difference (31) of the estimates. This is due to the fact that the cross-covariance term reflects a positive correlation between the estimation errors (this is always the case for linear systems).

The Test

The hypothesis testing for the **track-to-track association** *with the dependence accounted for* is done in the same manner as before in (28), except that the "smaller" covariance from (33) is used in the test statistic, which is, as before, the **normalized distance squared** between the estimates

$$D = \hat{\Delta}^{ij}(k)'[T^{ij}(k)]^{-1}\hat{\Delta}^{ij}(k) \qquad (34)$$

The Cross-Covariance of the Estimation Errors

The **cross-covariance recursion** for *synchronized sensors* can be shown to be (see Bar-Shalom et al. 2011)

$$P^{ij}(k|k) \triangleq E[\tilde{x}^i(k|k)\tilde{x}^j(k|k)']$$
$$= [I - W^i(k)H^i(k)]$$
$$\cdot [F(k-1)P^{ij}(k-1|k-1)F(k-1)'$$
$$+ Q(k-1)][I - W^j(k)H^j(k)]' \qquad (35)$$

This is a *linear recursion* – a Lyapunov-type equation – and its initial condition is, assuming the initial errors to be uncorrelated,

$$P^{ij}(0|0) = 0 \qquad (36)$$

This is a reasonable assumption in view of the fact that the initial estimates are usually based on the initial measurements, which were assumed to have independent errors.

The cross-covariance for the case of asynchronous sensors can be found in Bar-Shalom et al. (2011).

Summary and Future Directions

This entry surveyed the issues involved in data association (specifically M2TA and T2TA) with regard to multitarget-multisensor tracking systems.

The future developments in this topic will be in regard to the use of new feature variables and classification in data association (some preliminary results are in Bar-Shalom et al. (2011)).

Data Rate of Nonlinear Control Systems and Feedback Entropy

Christoph Kawan
Courant Institute of Mathematical Sciences, New York University, New York, USA

Abstract

Topological feedback entropy is a measure for the smallest information rate in a digital communication channel between the coder and the controller of a control system, above which the control task of rendering a subset of the state space invariant can be solved. It is defined purely in terms of the open-loop system without making reference to a particular coding and control scheme and can also be regarded as a measure for the inherent rate at which the system generates "invariance information."

Keywords

Communication constraints; Controlled invariance; Invariance entropy; Minimal data rates; Stabilization

Introduction

In the theory of networked control systems, the assumption of classical control theory that information can be transmitted within control loops instantaneously, lossless, and with arbitrary precision is no longer satisfied. Realistic mathematical models of many important real-world communication and control networks have to take into account general data rate constraints in the communication channels, time delays, partial loss of information, and variable network topologies. This raises the question about the smallest possible information rate above which a given control task can be solved. Though networked control systems can have a complicated topology, consisting of multiple sensors, controllers, and actuators, a first step towards understanding the problem of minimal data rates is to analyze the simplest possible network topology, consisting of one controller and one dynamical system connected by a digital channel with a certain rate in bits per unit time. There is a wealth of literature concerned with the problem of stabilizing a system under different assumptions about the specific coding and control scheme, in this context. However, with few exceptions, mainly linear systems (both deterministic and stochastic) have been considered. A comprehensive and detailed overview of this literature until 2007 can be found in the survey Nair et al. (2007). The first systematic approach to the problem of minimal data rates for set invariance and stabilization of (deterministic, nonlinear) control systems was presented in Nair et al. (2004), where the notion of *topological feedback entropy* was introduced. This quantity, defined in terms of the open-loop control system, is a measure for the smallest data rate a communication channel may have if the system is supposed to solve the control task of rendering a subset of the state space invariant. Other challenges that digital communication channels come along with are not yet taken into account here.

Feedback entropy was first introduced in Nair et al. (2004), using a similar approach via open covers as in the definition of topological entropy of for classical dynamical systems in Adler et al. (1965). In Colonius and Kawan (2009), a quantity named *invariance entropy* was defined which later turned out to be equivalent to the feedback entropy of Nair et al. (cf. Colonius et al. 2013). The notion of invariance entropy has been further

studied in the papers Kawan (2011a), Kawan (2011b), and Kawan (2011c). Several variations and generalizations have been introduced in Colonius (2010), Colonius (2012), Colonius and Kawan (2011), Da Silva (2013), and Hagihara and Nair (2013). The research monograph Kawan (2013) provides a comprehensive presentation of the results obtained so far in the deterministic case.

Definition

Topological feedback entropy is a nonnegative real-valued quantity which serves as a measure for the smallest possible data rate in a digital channel, connecting a coder to a controller, above which the controller is able to generate inputs which guarantee invariance of a given subset of the state space. In the literature, one finds several slightly differing versions. The original definition given in Nair et al. (2004) is (with minor modifications) as follows. Consider a discrete-time control system

$$x_{k+1} = F(x_k, u_k) = F_{u_k}(x_k), \qquad k \geq 0,$$

with $F : X \times U \to X$, where X is a topological space and U a nonempty set such that $F_u : X \to X$ is continuous for every $u \in U$. The transition map associated to this system is

$$\varphi : \mathbb{N}_0 \times X \times U^{\mathbb{N}_0} \to X,$$

$$\varphi(k, x, (u_n)) := F_{u_{k-1}} \circ \cdots \circ F_{u_1} \circ F_{u_0}(x).$$

A compact subset $K \subset X$ with nonempty interior is *(strongly) controlled invariant* if for every $x \in K$ there is an input $u \in U$ such that $F_u(x) \in$ int K. A triple $(\mathcal{A}, \tau, G)$ is called an *invariant open cover* of K if $\mathcal{A}$ is an open cover of K, τ is a positive integer, and $G : \mathcal{A} \to U^\tau$ is a map with components $G_0, G_1, \ldots, G_{\tau-1}$ which assign control values to all sets in $\mathcal{A}$ such that for every $A \in \mathcal{A}$ the finite sequence of controls $G(A)$ yields $\varphi(k, A, G(A)) \subset$ int K for $k = 1, 2, \ldots, \tau$. The *entropy of* $(\mathcal{A}, \tau, G)$ is defined as follows. For every sequence $\alpha = (A_i)_{i \geq 0}$ of sets in $\mathcal{A}$ one defines an associated sequence of controls by

$$\underline{u}(\alpha) = (u_0, u_1, u_2, \ldots) \quad \text{with } (u_l)_{l=(i-1)\tau}^{i\tau-1}$$
$$= G(A_{i-1}) \quad \text{for all } i \geq 0,$$

and for every $j \geq 1$ a set

$$B_j(\alpha) := \{x \in X \ : \ \varphi(i\tau, x, \underline{u}(\alpha)) \in A_i$$
$$\text{for } i = 0, 1, \ldots, j - 1\}.$$

The family $\mathcal{B}_j := \{B_j(\alpha) : \alpha \in \mathcal{A}^{\mathbb{N}_0}\}$ is an open cover of K. Letting $N(\mathcal{B}_j | K)$ denote the minimal cardinality of a finite subcover, the entropy of $(\mathcal{A}, \tau, G)$ is

$$h(\mathcal{A}, \tau, G) := \lim_{j \to \infty} \frac{1}{j\tau} \log_2 N(\mathcal{B}_j | K)$$
$$= \inf_{j \geq 1} \frac{1}{j\tau} \log_2 N(\mathcal{B}_j | K).$$

Finally, the topological feedback entropy (TFE) of K is given by

$$h_{\mathrm{fb}}(K) := \inf_{(\mathcal{A}, \tau, G)} h(\mathcal{A}, \tau, G),$$

where the infimum is taken over all invariant open covers of K.

A conceptually simpler but equivalent definition, introduced in Colonius and Kawan (2009), is the following. A subset $\mathcal{S} \subset U^\tau$ is called (τ, K)-*spanning* if for every $x \in K$ there is $\underline{u} \in \mathcal{S}$ with $\varphi(k, x, \underline{u}) \in$ int K for $k = 1, \ldots, \tau$. Writing $r_{\mathrm{inv}}(\tau, K)$ for the minimal cardinality of such a set, it can be shown that

$$h_{\mathrm{fb}}(K) = \lim_{\tau \to \infty} \frac{1}{\tau} \log_2 r_{\mathrm{inv}}(\tau, K)$$
$$= \inf_{\tau \geq 1} \frac{1}{\tau} \log_2 r_{\mathrm{inv}}(\tau, K).$$

This definition and several variations of it are mostly referred to by the name *invariance entropy* instead of feedback entropy. The intuition behind this definition is that a controller which receives a certain amount of information about the state, say n bits, can generate at most 2^n different control sequences to steer the system on a finite time interval and hence, the number of control sequences needed to

accomplish the control task on this interval is a measure for the necessary amount of information.

The different variations of feedback or invariance entropy which can be found in the literature are briefly summarized as follows. For simplicity, in this entry we refer to several of these variations by the name *(topological) feedback entropy*:

(i) Instead of requiring that trajectories enter the interior of K after one step of time, one can allow for a waiting time τ_0 before entering $\text{int} K$.

(ii) One can require that trajectories stay in K instead of $\text{int} K$ or that they stay in an arbitrarily small neighborhood of K, respectively.

(iii) One can restrict the set of initial states to a subset of $K' \subset K$. In this case, a set $\mathcal{S}$ of control sequences is (τ, K', K)-spanning if for every $x \in K'$ there is $\underline{u} \in \mathcal{S}$ with $\varphi(k, x, \underline{u}) \in \text{int} K$ for $k = 1, \ldots, \tau$.

(iv) Feedback entropy can be defined for other classes of systems, e.g., continuous-time deterministic systems, random control systems, or systems with piecewise continuous right-hand sides.

There is also a local version of topological feedback entropy (LTFE) which measures the smallest data rate for local uniform asymptotic stabilization at an equilibrium. Also for other control tasks there have been attempts to define corresponding versions of feedback or invariance entropy.

Comparison to Topological Entropy

Though there are similarities in the definitions of TFE and topological entropy of dynamical systems, which also reflect in similar properties, there is no direct relation between these two quantities. Topological entropy detects exponential complexity in the orbit structure of a dynamical system. In contrast, TFE measures the complexity of the control task to keep a system in a subset of the state space by applying appropriate inputs. If no escape from this subset is possible, the TFE is zero, no matter how complicated the orbit structure is. Hence, topological entropy is sensitive to the local behavior of the system,

while TFE in general is not. Interpreted in terms of information rates, topological entropy is a measure for the largest average rate of information about the initial state a dynamical system can generate. TFE measures the smallest rate of information about the state of the system above which a controller is able to render the set invariant. It should also be mentioned that topological entropy was first introduced as a topological counterpart of the measure-theoretic entropy defined by Kolmogorov and Sinai, and that the two notions are related by the variational principle, which asserts that the topological entropy is the supremum of the measure-theoretic entropies with respect to all invariant probability measures of the given system. For TFE, so far no convincing measure-theoretic approach exists. An excellent survey on the entropy theory of dynamical systems can be found in Katok (2007).

The Data Rate Theorem

The *data rate theorem* for the TFE confirms that the infimal data rate in a coding and control loop which guarantees strong controlled invariance of a set K is equal to $h_{\text{fb}}(K)$. More precisely, suppose that a sensor which measures the state of the system at discrete times $\tau_k = k\tau, k = 0, 1, 2, \ldots$, is connected to a coder which at time τ_k has a finite alphabet S_k of symbols available. The measured state is coded by use of this alphabet and the corresponding symbol is sent via a noiseless digital channel to a controller which generates an input sequence of length τ. This sequence is used to steer the system until the next symbol arrives at time τ_{k+1}. The associated *asymptotic average bit rate*, which depends on the sequence $S = (S_k)_{k \geq 0}$ of coding alphabets, is given by

$$R(S) = \lim_{k \to \infty} \frac{1}{k\tau} \sum_{i=0}^{k-1} \log_2 |S_i|.$$

If the limit does not exist, one may replace it with $\liminf$ or $\limsup$. The data rate theorem establishes the equality

$$h_{\text{fb}}(K) = \inf_S R(S),$$

where the infimum is taken over all coding and control loops which guarantee strong controlled invariance of K, i.e., for initial states in K they generate trajectories $(x_k)_{k \geq 0}$ with $x_k \in \text{int} K$ for $k = 1, 2, \ldots$. Similar data rate theorems can be proved for other variants of feedback entropy. In particular, the data rate theorem for the LTFE asserts that the infimal bit rate for local uniform asymptotic stabilization at an equilibrium is given by the LTFE. Proofs of different data rate theorems can be found in Nair et al. (2004), Hagihara and Nair (2013), and Kawan (2013).

Estimates and Formulas

Linear Systems

For linear systems, under reasonable assumptions, the feedback entropy is given by the sum of the unstable eigenvalues of the dynamical matrix, i.e., if the system is given by $x_{k+1} = Ax_k + Bu_k$, then

$$h_{\text{fb}}(K) = \sum_{\lambda \in \text{Sp}(A)} \max \left\{ 0, n_\lambda \log_2 |\lambda| \right\}, \quad (1)$$

where $\text{Sp}(A)$ denotes the spectrum of A and n_λ is the algebraic multiplicity of the eigenvalue λ (cf. Colonius and Kawan 2009). It is worth to mention that the TFE therefore coincides with the topological entropy of the uncontrolled system $x_{k+1} = Ax_k$, as defined by Bowen for maps on non-compact metric spaces (cf. Bowen 1971). However, this is a special property of linear systems and is related to the facts that (i) there is no difference between the local and the global dynamical behavior of uncontrolled linear systems and that (ii) the control sequence does not affect the exponential complexity of the dynamics, since it only appears as an additive term in the transition map of the system. Formula (1) is in correspondence with several former results on minimal data rates for stabilization of linear systems. Thinking of the definition of feedback entropy via spanning sets of control sequences, its interpretation is that in order to guarantee invariance of a bounded set, the only reason for exponential growth of the number of necessary

inputs as time increases is the volume expansion of the open-loop system in the unstable subspace.

Upper Bounds Under Controllability Assumptions

If the state space of the control system is a differentiable manifold and the right-hand side is continuously differentiable, under certain controllability assumptions upper bounds for the feedback entropy can be formulated in terms of the Lyapunov exponents of periodic trajectories (for the concept of Lyapunov exponents, see, e.g., Barreira and Valls 2008) (cf. Kawan 2011b, 2013; Nair et al. 2004). More precisely, if there is a periodic trajectory in the interior of the given set K such that the linearization along this trajectory is controllable, and if complete approximate controllability holds on the interior of K (cf. Colonius and Kliemann 2000), then

$$h_{\text{fb}}(K) \leq \sum_\lambda \max\{0, n_\lambda \lambda\}, \quad (2)$$

where the sum is taken over all Lyapunov exponents λ of the periodic trajectory and n_λ denotes the multiplicity of λ. Using the definition of feedback entropy in terms of (τ, K)-spanning sets, one can prove this by constructing spanning sets of control functions which first steer all initial states in K into a small neighborhood of a point on the given periodic orbit and then, by use of local controllability, keep the corresponding trajectories in a neighborhood of the periodic trajectory for arbitrary future times. Similar ideas first have been used in Nair et al. (2004) to prove that the LTFE at an equilibrium is given by the sum of the unstable eigenvalues of the linearization about this equilibrium. For systems given by differential equations the upper estimate (2) can be improved under additional regularity assumptions. Assuming that the system is smooth and satisfies the strong jet accessibility rank condition (cf. Coron 1994), one can show that both assumptions, controllability of the linearization and periodicity, can be omitted. The only restriction that remains is that the trajectory must not leave a compact subset of the interior of K. However, in the case of nonperiodic trajectories, the sum

of the positive Lyapunov exponents has to be replaced by the maximal Lyapunov exponent of the induced linear flow on the exterior bundle of the manifold. For control-affine systems, strong jet accessibility can be weakened to local accessibility. In general, it is unlikely that such upper bounds are tight, since they are related to very specific control strategies for making the given set invariant.

Lower Bounds, Volume Growth Rates, and Escape Rates

A general approach to obtain lower bounds of feedback entropy is via a volume growth argument, which in its simplest form works as follows. Every (τ, K)-spanning set $\mathcal{S}$ defines a cover of K, consisting of the sets (cf. Kawan 2011a,c)

$$K_{\tau,\underline{u}} = \{x \in K \ : \ \varphi(k, x, \underline{u}) \in \mathrm{int}K,$$
$$1 \le k \le \tau\}, \qquad \underline{u} \in \mathcal{S}.$$

It follows that $\varphi_{\tau,\underline{u}}(K_{\tau,\underline{u}}) \subset K$ and hence, since K is bounded, the volume expansion under $\varphi_{\tau,\underline{u}} = \varphi(\tau, \cdot, \underline{u})$ gives upper bounds for the volumes of the sets $K_{\tau,\underline{u}}$, which result in a lower bound for the number of these sets. For instance, the lower estimate in (1) can be established by applying this argument to the system which arises by projection of the given linear system to the unstable subspace of the uncontrolled part $x_{k+1} = Ax_k$. A refinement of this idea also leads to lower estimates of feedback entropy for inhomogeneous bilinear systems in terms of volume growth rates or Lyapunov exponents on unstable bundles, respectively. For nonlinear systems, in general only very rough estimates can be obtained by this method. However, a variation of the volume growth argument leads to a lower bound of the form

$$h_{\mathrm{fb}}(K) \ge -\liminf_{\tau \to \infty} \frac{1}{\tau} \log \sup_{\underline{u}} \mu(K_{\tau,\underline{u}}),$$

where μ denotes a reference measure on the state space. The right-hand side of this inequality can be considered as a uniform *escape rate* from the set K, which under sufficiently strong hyperbolicity assumptions can be estimated in terms of other quantities such as Lyapunov exponents and dynamical entropies. Key references for escape rates in the classical theory of dynamical systems are (Young (1990) and Demers and Young (2006)).

Summary and Future Directions

The theory of feedback entropy for finite-dimensional deterministic systems is very far from being complete. The currently available results only give valuable information in very regular situations, and even those are not fully understood. For the further development of this theory, it will be necessary to combine control-theoretic methods with techniques from different fields such as classical, random, and nonautonomous dynamical systems. Some of the main focuses of future research will probably be the following:

- The generalization of feedback entropy to more complex network topologies
- The formulation of a feedback entropy theory for stochastic systems
- The development of a probabilistic (resp. measure-theoretic) version of feedback entropy for both deterministic and stochastic systems, which is related to the topological version via a variational principle
- The numerical computation of feedback entropy

Deterministic Description of Biochemical Networks

Jörg Stelling and Hans-Michael Kaltenbach
ETH Zürich, Basel, Switzerland

Abstract

Mathematical models of living systems are often based on formal representations of the underlying reaction networks. Here, we present the basic concepts for the deterministic nonspatial treatment of such networks. We describe the most prominent approaches for steady-state and dynamic analysis using systems of ordinary differential equations.

Keywords

Michaelis-Menten kinetics; Reaction networks; Stoichiometry

Introduction

A biochemical network describes the interconversion of biochemical species such as proteins or metabolites by chemical reactions. Such networks are ubiquitous in living cells, where they are involved in a variety of cellular functions such as conversion of metabolites into energy or building material of the cell, detection and processing of external and internal signals of nutrient availability or environmental stress, and regulation of genetic programs for development.

Reaction Networks

A biochemical network can be modeled as a dynamic system with the chemical concentration of each species taken as the states and dynamics described by the changes in species concentrations as they are converted by reactions. Assuming that species are homogeneously distributed in the reaction volume and that copy numbers are sufficiently high, we may ignore spatial and stochastic

effects and derive a system of ordinary differential equations (ODEs) to model the dynamics.

Formally, a biochemical network is given by r reactions $R_1, \ldots, R_r$ acting on n different chemical species $S_1, \ldots, S_n$. Reaction R_j is given by

$$R_j : \ \alpha_{1,j} S_1 + \cdots + \alpha_{n,j} S_n \longrightarrow \beta_{1,j} S_1$$
$$+ \cdots + \beta_{n,j} S_n \ ,$$
where $\alpha_{i,j}, \beta_{i,j} \in \mathbb{N}$ are called the *molecularities* of the species in the reaction. Their differences form the *stoichiometric matrix* $\mathbf{N} = (\beta_{i,j} - \alpha_{i,j})_{i=1\ldots n, j=1\ldots r}$, with $N_{i,j}$ describing the net effect of one turnover of R_j on the copy number of species S_i. The jth column is also called the *stoichiometry* of reaction R_j. The system can be opened to an un-modeled environment by introducing inflow reactions $\emptyset \rightarrow S_i$ and outflow reactions $S_i \rightarrow \emptyset$.

For example, consider the following reaction network:

$$R_1 : \qquad E + S \rightarrow E \cdot S$$
$$R_2 : \qquad E \cdot S \rightarrow E + S$$
$$R_3 : \qquad E \cdot S \rightarrow E + P$$
Here, an enzyme E (a protein that acts as a catalyst for biochemical reactions) binds to a substrate species S, forming an intermediate complex $E \cdot S$ and subsequently converting S into a product P. Note that the enzyme-substrate binding is reversible, while the conversion to a product is irreversible. This network contains $r = 3$ reactions interconverting $n = 4$ chemical species $S_1 = S$, $S_2 = P$, $S_3 = E$, and $S_4 = E \cdot S$. The stoichiometric matrix is

$$\mathbf{N} = \begin{pmatrix} -1 & +1 & 0 \\ 0 & 0 & +1 \\ -1 & +1 & +1 \\ +1 & -1 & -1 \end{pmatrix} \ .$$

Dynamics

Let $\mathbf{x}(t) = (x_1(t), \ldots, x_n(t))^T$ be the vector of concentrations, that is, $x_i(t)$ is the concentration of S_i at time t. Abbreviating this state vector as $\mathbf{x}$

by dropping the explicit dependence on time, its dynamics is governed by a system of n ordinary differential equations:

$$\frac{d}{dt}\mathbf{x} \ = \ \mathbf{N} \cdot \mathbf{v}(\mathbf{x}, \mathbf{p}) \ . \tag{1}$$

Here, the *reaction rate* vector $\mathbf{v}(\mathbf{x}, \mathbf{p}) = (v_1(\mathbf{x}, \mathbf{p}_1), \ldots, v_r(\mathbf{x}, \mathbf{p}_r))^T$ gives the rate of conversion of each reaction per unit-time as a function of the current system state and of a set of parameters $\mathbf{p}$.

A typical reaction rate is given by the *mass-action rate law*

$$v_j(\mathbf{x}, \mathbf{p}_j) = k_j \cdot \prod_{i=1}^{n} x_i^{\alpha_{i,j}} \ ,$$

where the rate constant $k_j > 0$ is the only parameter and the rate is proportional to the concentration of each species participating as an educt (consumed component) in the respective reaction.

Equation (1) decomposes the system into a time-independent and linear part described solely by the topology and stoichiometry of the reaction network via $\mathbf{N}$ and a dynamic and typically nonlinear part given by the reaction rate laws $\mathbf{v}(\cdot, \cdot)$. One can define a directed graph of the network with one vertex per state and take $\mathbf{N}$ as the (weighted) incidence matrix. Reaction rates are then properties of the resulting edges. In essence, the equation describes the change of each species' concentration as the sum of the current reaction rates. Each rate is weighted by the molecularity of the species in the corresponding reaction; it is negative if the species is consumed by the reaction and positive if it is produced.

Using mass-action kinetics throughout, and using the species name instead of the numeric subscript, the reaction rates and parameters of the example network are given by

$$v_1(\mathbf{x}, \mathbf{p}_1) = k_1 \cdot x_E(t) \cdot x_S(t)$$
$$v_2(\mathbf{x}, \mathbf{p}_2) = k_2 \cdot x_{E \cdot S}(t)$$
$$v_3(\mathbf{x}, \mathbf{p}_3) = k_3 \cdot x_{E \cdot S}(t)$$
$$\mathbf{p} = (k_1, k_2, k_3)$$

The system equations are then

$$\frac{d}{dt}x_S = -k_1 \cdot x_S \cdot x_E + k_2 \cdot x_{E \cdot S}$$

$$\frac{d}{dt}x_P = k_3 \cdot x_{E \cdot S}$$

$$\frac{d}{dt}x_E = -k_1 \cdot x_S \cdot x_E + k_2 \cdot x_{E \cdot S} + k_3 \cdot x_{E \cdot S}$$

$$\frac{d}{dt}x_{E \cdot S} = k_1 \cdot x_S \cdot x_E - k_2 \cdot x_{E \cdot S} - k_3 \cdot x_{E \cdot S} \ .$$

Steady-State Analysis

A reaction network is in *steady state* if the production and consumption of each species are balanced. Steady-state concentrations $\mathbf{x}^*$ then satisfy the equation

$$\mathbf{0} = \mathbf{N} \cdot \mathbf{v}(\mathbf{x}^*, \mathbf{p}) \ .$$

Computing steady-state concentrations requires explicit knowledge of reaction rates and their parameter values. For biochemical reaction networks, these are often very difficult to obtain. An alternative is the computation of *steady-state fluxes* $\mathbf{v}^*$, which only requires solving the system of homogeneous linear equations

$$\mathbf{0} = \mathbf{N} \cdot \mathbf{v} \ . \tag{2}$$

Lower and upper bounds v_i^l, v_i^u for each flux v_i can be given such that $v_i^l \leq v_i \leq v_i^u$; an example is an irreversible reaction R_i which implies $v_i^l = 0$. The set of all feasible solutions then forms a pointed, convex, polyhedral *flux cone* in $\mathbb{R}^r$. The rays spanning the flux cone correspond to *elementary flux modes (EFMs)* or *extreme pathways (EPs)*, minimal subnetworks that are already balanced. Each feasible steady-state flux can be written as a nonnegative combination

$$\mathbf{v}^* = \sum_i \lambda_i \cdot \mathbf{e}_i, \quad \lambda_i \geq 0$$

of EFMs $\mathbf{e}_1, \mathbf{e}_2, \ldots,$ where the λ_i are the corresponding weights.

Even if in steady state, living cells grow and divide. Growth of a cell is often described by a combination of fluxes $\mathbf{b}^T \cdot \mathbf{v}$, the total production rate of relevant metabolites to form new biomass. The *biomass function* given by $\mathbf{b} \in \mathbb{R}^r$ is determined experimentally. The technique of *flux balance analysis (FBA)* then solves the linear program

$$\max_{\mathbf{v}} \ \mathbf{b}^T \cdot \mathbf{v}$$

subject to

$$\mathbf{0} = \mathbf{N} \cdot \mathbf{v}$$

$$v_i^l \leq v_i \leq v_i^u$$

to yield a feasible flux vector that balances the network while maximizing growth. Alternative objective functions have been proposed, for instance, for higher organisms that do not necessarily maximize the growth of each cell.

Quasi-Steady-State Analysis

In many reaction mechanisms, a *quasi-steady-state assumption (QSSA)* can be made, postulating that the concentration of some of the involved species does not change. This assumption is often justified if reaction rates differ hugely, leading to a time scale separation, or if some concentrations are very high, such that their change is negligible for the mechanism. A typical example is the derivation of *Michaelis-Menten kinetics*, which corresponds to our example network. There, we may assume that the concentration of the intermediate species $E \cdot S$ stays approximately constant on the time scale of the overall conversion of substrate into product and that the substrate, at least initially, is in much larger abundance than the enzyme. On the slower time scale, this leads to the *Michaelis-Menten rate law*:

$$v_P = \frac{d}{dt}x_P(t) = \frac{v_{\max} \cdot x_S(t)}{K_m + x_S(t)} \ ,$$

with a maximal rate $v_{\max} = k_3 \cdot x_E^{\text{tot}}$, where x_E^{tot} is the total amount of enzyme and the Michaelis-Menten constant $K_m = (k_2 + k_3)/k_1$ as a direct relation between substrate concentration and production rate. This approximation reduces the number of states by two. Both parameters

of the Michaelis-Menten rate law are also better suited for experimental determination: v_{max} is the highest rate achievable and K_m corresponds to the substrate concentration that yields a rate of $v_{max}/2$.

Cooperativity and Ultra-sensitivity

In the Michaelis-Menten mechanism, the production rate gradually increases with increasing substrate concentration, until saturation (Fig. 1; $h = 1$). A different behavior is achieved if the enzyme has several binding sites for the substrate and these sites interact such that occupation of one site alters the affinity of the other sites positively or negatively, phenomena known as positive and negative cooperativity, respectively. With QSSA arguments as before, the fraction of enzymes completely occupied by substrate molecules at time t is given by

$$ v = \frac{v_{max} \cdot x_S(t)}{K^h + x_S^h(t)} $$

where $K > 0$ is a constant and $h > 0$ is the *Hill coefficient*. The Hill coefficient determines the shape of the response with increasing substrate concentration: a coefficient of $h > 1$ ($h < 1$) indicates positive (negative) cooperativity; $h = 1$ reduces to the Michaelis-Menten mechanism. With increasing coefficient h, the response changes from gradual to switch-like, such that the transition from low to high response becomes more rapid as indicated in Fig. 1. This phenomenon is also known as *ultra-sensitivity*.

Constrained Dynamics

Due to the particular structure of the system equation (1), the trajectories $\mathbf{x}(t)$ of the network with $\mathbf{x}_0 = \mathbf{x}(0)$ are confined to the *stoichiometric subspace*, the intersection of $\mathbf{x}_0 + \text{Img}\mathbf{N}$ with the positive orthant. *Conservation relations* that describe conservation of mass are thus found as solutions to

$$ \mathbf{c}^T \cdot \mathbf{N} = \mathbf{0} \;, $$

and two initial conditions $\mathbf{x}_0, \mathbf{x}_0'$ lead to the same stoichiometric subspace if $\mathbf{c}^T \cdot \mathbf{x}_0 = \mathbf{c}^T \cdot \mathbf{x}_0'$. This allows for the analysis of, for example, bistability using only the reaction network structure.

Summary and Future Directions

Reactions networks, even in simple cells, typically encompass thousands of components and reactions, resulting in potentially high-dimensional nonlinear dynamic systems. In contrast to engineered systems, biology is characterized by a high degree of uncertainty of both model structure and parameter values. Therefore, system identification is a central problem in this domain. Specifically, advanced methods for model topology and parameter identification as well as for uncertainty quantification need to be developed that take into account the very limited observability of biological systems. In addition, biological systems operate on multiple time, length, and concentration scales. For example, genetic regulation usually operates on the time scale of minutes and involves very few molecules, whereas metabolism is significantly faster and states are well approximated by species

Deterministic Description of Biochemical Networks, Fig. 1 Responses for cooperative enzyme reaction with Hill coefficient $h = 1, 3, 10$, respectively. All other parameters are set to 1
concentrations. Corresponding systematic frameworks for multiscale modeling, however, are currently lacking.

Diagnosis of Discrete Event Systems

Stéphane Lafortune
Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MI, USA

Abstract

We discuss the problem of event diagnosis in partially observed discrete event systems. The objective is to infer the past occurrence, if any, of an unobservable event of interest based on the observed system behavior and the complete model of the system. Event diagnosis is performed by diagnosers that are synthesized from the system model and that observe the system behavior at run-time. Diagnosability analysis is the off-line task of determining which events of interest can be diagnosed at run-time by diagnosers.

Keywords

Diagnosability; Diagnoser; Fault diagnosis; Verifier

Introduction

In this entry, we consider discrete event systems that are partially observable and discuss the two related problems of event diagnosis and diagnosability analysis. Let the DES of interest be denoted by M with event set E. Since M is partially observable, its set of events E is the disjoint union of a set of *observable events*, denoted by E_o, with a set of *unobservable* events, denoted by E_{uo}: $E = E_o \cup E_{uo}$. At this point, we do not specify how M is represented; it could be an automaton or a Petri net. Let L_M be the set of all strings of events in E that the DES M can execute, i.e., the (untimed) language model of the system; cf. the related entries, ▶ Models for Discrete Event Systems: An Overview, ▶ Supervisory Control of Discrete-Event Systems, and ▶ Modeling, Analysis, and Control with Petri Nets. The set E_{uo} captures the fact that the set of sensors attached to the DES M is limited and may not cover all the events of the system. Unobservable events can be internal system events that are not directly "seen" by the monitoring agent that observes the behavior of M for diagnosis purposes. They can also be fault events that are included in the system model but are not directly observable by a dedicated sensor. For the purpose of diagnosis, let us designate a specific unobservable event of interest and denote it by $d \in E_{uo}$. Event d could be a fault event or some other significant event that is unobservable.

Before we can state the problem of event diagnosis, we need to introduce some notation. E^* is the set of all strings of any length $n \in \mathbb{N}$ that can be formed by concatenating elements of E. The unique string of length $n = 0$ is denoted by ε and is the identity element of concatenation. As in article ▶ Supervisory Control of Discrete-Event Systems, section "Supervisory Control Under Partial Observations," we define the projection function $P : E^* \rightarrow E_o^*$ that "erases" the unobservable events in a string and replaces them by ε. The function P is naturally extended to a set of strings by applying it to each string in the set, resulting in a set of projected strings. The observed behavior of M is the language $P(L_M)$ over event set E_o.

The problem of *event diagnosis*, or simply *diagnosis*, is stated as follows: how to infer the past occurrence of event d when observing strings in $P(L_M)$ at run-time, i.e., during the operation of the system? This is model-based inferencing, i.e., the monitoring agent knows L_M and the partition $E = E_o \cup E_{uo}$, and it observes strings in $P(L_M)$. When there are multiple events of interest, d_1 to d_n, and these events are *fault* events, we have a problem of *fault diagnosis*. In this case, the objective is not only to determine that a fault has occurred (commonly referred to as "fault detection") but also to identify which fault has occurred, namely, which event d_i (commonly referred to as "fault isolation and identification"). Fault diagnosis requires that L_M contains not only the nominal or fault-free behavior of the system but also its behavior after the occurrence of each fault event d_i of interest, i.e., its faulty behavior. Event d_i is typically a fault of a component that leads to degraded behavior on the part of the system. It is not a catastrophic failure that would cause the system to completely stop operating, as such a failure would be immediately observable. The decision on which fault events d_i, along with their associated faulty behaviors, to include in the complete model L_M is a design one that is based on practical considerations related to the diagnosis objectives.

A complementary problem to event diagnosis is that of *diagnosability analysis*. Diagnosability analysis is the off-line task of determining, on the basis of L_M and of E_o and E_{uo}, if any and all occurrences of the given event of interest d will eventually be diagnosed by the monitoring agent that observes the system behavior.

Event diagnosis and diagnosability analysis arise in numerous applications of systems that are modeled as DES. We mention a few application areas where DES diagnosis theory has been employed. In heating, ventilation, and air-conditioning systems, components such as valves, pumps, and controllers can fail in degraded modes of operation, such as a valve gets stuck open or stuck closed or a pump or controller gets stuck on or stuck off. The available sensors may not directly observe these faults, as the sensing abilities are limited. Fault diagnosis techniques are essential, since the components of the system are often not easily accessible. In monitoring communication networks, faults of certain transmitters or receivers are not directly observable and must be inferred from the set of successful communications and the topology of the network. In document processing systems, faults of internal components can lead to jams in the paper path or a decrease in image quality, and while the paper jam or the image quality is itself observable, the underlying fault may not be as the number of internal sensors is limited.

Without loss of generality, we consider a single event of interest to diagnose, d. When there are multiple events to diagnose, the methodologies that we describe in the remaining of this entry can be applied to each event of interest d_i, $i = 1, \ldots n$, individually; in this case, the other events of interest d_j, $j \neq i$ are treated the same as the other unobservable events in the set E_{uo} in the process of model-based inferencing.

Problem Formulation

Event Diagnosis

We start with a general language-based formulation of the event diagnosis problem. The information available to the agent that monitors the system behavior and performs the task of event diagnosis is the language L_M and the set of observable events E_o, along with the specific

string $t \in P(L_M)$ that it observes at run-time. The actual string generated by the system is $s \in L_M$ where $P(s) = t$. However, as far as the monitoring agent is concerned, the actual string that has occurred could be any string in $P^{-1}(t) \cap L_M$, where P^{-1} is the inverse projection operation, i.e., $P^{-1}(t)$ is the set of all strings $s_t \in E^*$ such that $P(s_t) = t$. Let us denote this estimate set by $\mathcal{E}(t) = P^{-1}(t) \cap L_M$, where "$\mathcal{E}$" stands for "estimate." If a string $s \in L_M$ contains event d, we write that $d \in L_M$; otherwise, we write that $d \notin L_M$.

The event diagnosis problem is to synthesize a diagnostic engine that will automatically provide the following answers from the observed t and from the knowledge of L_M and E_o:

1. **Yes**, if and only if $d \in s$ for all $s \in \mathcal{E}(t)$.
2. **No**, if and only if $d \notin s$ for all $s \in \mathcal{E}(t)$.
3. **Maybe**, if and only if there exists $s_Y, s_N \in \mathcal{E}(t)$ such that $d \in s_Y$ and $d \notin s_N$.

As defined, $\mathcal{E}(t)$ is a string-based estimate. In section "Diagnosis of Automata," we discuss how to build a finite-state structure that will encode the desired answers for the above three cases when the DES M is modeled by a deterministic finite-state automaton. The resulting structure is called a *diagnoser automaton*.

Diagnosability Analysis

Diagnosability analysis consists in determining, a priori, if any and all occurrences of event d in L_M will eventually be diagnosed, in the sense that if event d occurs, then the diagnostic engine is guaranteed to eventually issue the decision "Yes." For the sake of technical simplicity, we assume hereafter that L_M is a *live* language, i.e., any trace in L_M can always be extended by one more event. In this context, we would not want the diagnostic engine to issue the decision "Maybe" for an arbitrarily long number of event occurrences after event d occurs. When this outcome is possible, we say that event d is *not diagnosable* in language L_M.

The property of *diagnosability* of DES is defined as follows. In view of the liveness assumption on language L_M, any string s_Y' that contains event d can always be extended to a longer string, meaning that it can be made "arbitrarily long"

after the occurrence of d. That is, for any s_Y' in L_M and for any $n \in \mathbb{N}$, there exists $s_Y = s_Y' t \in L_M$ where the length of t is equal to n. Event d is *not* diagnosable in language L_M if there exists such a string s_Y together with a second string s_N that does not contain event d, and such that $P(s_Y) = P(s_N)$. This means that the monitoring agent is unable to distinguish between s_Y and s_N, yet, the number of events after an occurrence of d can be made arbitrarily large in s_Y, thereby preventing diagnosis of event d within a finite number of events after its occurrence. On the other hand, if no such pair of strings (s_Y, s_N) exists in L_M, then event d is diagnosable in L_M. (The mathematically precise definition of diagnosability is available in the literature cited at the end of this entry.)

Diagnosis of Automata

We recall the definition of a deterministic finite-state automaton, or simply automaton, from article ▶ Models for Discrete Event Systems: An Overview, with the addition of a set of unobservable events as in section "Supervisory Control Under Partial Observations" in article ▶ Supervisory Control of Discrete-Event Systems. The automaton, denoted by G, is a four-tuple $G = (X, E, f, x_0)$ where X is the finite set of states, E is the finite set of events partitioned into $E = E_o \cup E_{uo}$, x_0 is the initial state, and f is the deterministic partial transition function $f : X \times E \to X$ that is immediately extended to strings $f : X \times E^* \to X$. For a DES M represented by an automaton G, L_M is the language generated by automaton G, denoted by $\mathcal{L}(G)$ and formally defined as the set of all strings for which the extended f is defined. It is an infinite set if the transition graph of G has one or more cycles. In view of the liveness assumption made on L_M in the preceding section, G has no reachable deadlocked state, i.e., for all $s \in E^*$ such that $f(x, s)$ is defined, then there exists $\sigma \in E$ such that $f(x, s\sigma)$ is also defined.

To synthesize a diagnoser automaton that correctly performs the diagnostic task formulated in the preceding section, we proceed as follows.

First, we perform the parallel composition (denoted by ||) of G with the two-state *label automaton* A_{label} that is defined as follows. $A_{label} = (\{N, Y\}, \{d\}, f_{label}, N)$, where f_{label} has two transitions defined: (i) $f_{label}(N, d) = Y$ and (ii) $f_{label}(Y, d) = Y$. The purpose of A_{label} is to record the occurrence of event d, which causes a transition to state Y. By forming $G_{labeled} = G||A_{label}$, we record in the states of $G_{labeled}$, which are of the form (x_G, x_A), if the first element of the pair, state $x_G \in X$, was reached or not by executing event d at some point in the past: if d was executed, then $x_A = Y$, otherwise $x_A = N$. (We refer the reader to Chap. 2 in Cassandras and Lafortune (2008) for the formal definition of parallel composition of automata.) By construction, $\mathcal{L}(G_{labeled}) = \mathcal{L}(G)$.

The second step of the construction of the diagnoser automaton is to build the *observer* of $G_{labeled}$, denoted by $Obs(G_{labeled})$, with respect to the set of observable events E_o. (We refer the reader to Chap. 2 in Cassandras and Lafortune (2008) for the definition of the observer automaton and for its construction.) The construction of the observer involves the standard subset construction algorithm for nondeterministic automata in automata theory; here, the unobservable events are the source of nondeterminism, since they effectively correspond to ε-transitions. The diagnoser automaton of G with respect to E_o is defined as $Diag(G) = Obs(G||A_{label})$. Its event set is E_o.

The states of $Diag(G)$ are *sets* of state pairs of the form (x_G, x_A) where x_A is either N or Y. Examination of the state of $Diag(G)$ reached by string $t \in P[\mathcal{L}(G)]$ provides the answers to the event diagnosis problem. Let us denote that state by x_{Diag}^t. Then:

1. The diagnostic decision is **Yes** if *all* state pairs in x_{Diag}^t have their second component equal to Y; we call such a state a "Yes-state" of $Diag(G)$.
2. The diagnostic decision is **No** if *all* state pairs in x_{Diag}^t have their second component equal to N; we call such a state a "No-state" of $Diag(G)$.
3. The diagnostic decision is **Maybe** if there is at least one state pair in x_{Diag}^t whose second

component is equal to Y and at least one state pair in x_{Diag}^t whose second component is equal to N; we call such a state a "Maybe-state" of $Diag(G)$.

To perform run-time diagnosis, it therefore suffices to examine the current state of $Diag(G)$. Note that $Diag(G)$ can be computed off-line from G and stored in memory, so that run-time diagnosis requires only updating the new state of $Diag(G)$ on the basis of the most recent observed event (which is necessarily in E_o). If storing the entire structure of $Diag(G)$ is impractical, its current state can be computed on-the-fly on the basis of the most recent observed event and of the transition structure of $G_{labeled}$; this involves one step of the subset construction algorithm.

As a simple example, consider the automaton G_1 shown in Fig. 1, where $E_{uo} = \{d\}$. The occurrence of event d changes the behavior of the system such that event c does not cause a return to the initial state 1 (identified by incoming arrow); instead, the system gets stuck in state 3 after d occurs.

Its diagnoser is depicted in Fig. 2. It contains one Yes-state, state $\{(3, Y)\}$ (abbreviated as "3Y" in the figure), one No-state, and two Maybe-states (similarly abbreviated). Two consecutive occurrences of event c, or an occurrence of b right after c, both indicate that the system must be in state 3,

Diagnosis of Discrete Event Systems, Fig. 3
Automaton G_2

i.e., that event d must have occurred; this is captured by the two transitions from Maybe-state $\{(1, N), (3, Y)\}$ to the Yes-state in Diag(G_1). As a second example, consider the automaton G_2 shown in Fig. 3, where the self-loop b at state 3 in G_1 has been removed. Its diagnoser is shown in Fig. 4.

Diagnoser automata provide as much information as can be inferred, from the available observations and the automaton model of the system, regarding the past occurrence of unobservable event d. However, we may want to answer the

question: Can the occurrence of event d always be diagnosed? This is the realm of diagnosability analysis discussed in the next section.

Diagnosability Analysis of Automata

As mentioned earlier, diagnosability analysis consists in determining, a priori, if any and all occurrences of event d in L_M will eventually be diagnosed. In the case of diagnoser automata, we do not want Diag(G) to loop forever in a cycle of Maybe-states and never enter a Yes-state if event d has occurred, as happens in the diagnoser in Fig. 2 for the string adb^n when n gets arbitrarily large. In this case, Diag(G_1) loops in Maybe-state $\{(2, N), (3, Y)\}$, and the occurrence of d goes undetected. This shows that event d is not diagnosable in G_1; the counterexample is provided by strings $s_Y = adb^n$ and $s_N = ab^n$.

For systems modeled as automata, diagnosability can be tested with quadratic time complexity in the size of the state space of G by forming a so-called twin-automaton (also called "verifier") where G is parallel composed with itself, but synchronization is only enforced on *observable* events, allowing arbitrary interleavings of unobservable events. The test for diagnosability reduces to detection of cycles that occur after

event d in the twin-automaton. It can be verified that for automaton G_2 in our example, event d is diagnosable. Indeed, it is clear from the structure of G_2 that Diag(G_2) in Fig. 4 will never loop in Maybe-state $\{(2, N), (3, Y)\}$ if event d occurs; rather, after d occurs, G_2 can only execute c events, and after two such events, Diag(G_2) enters Yes-state $\{(3, Y)\}$.

Note that diagnosability will not hold in an automaton that contains a cycle of unobservable events after the occurrence of event d, although this is not the only instance where the property is violated, as we saw in our simple example.

Diagnosis and Diagnosability Analysis of Petri Nets

There are several approaches for diagnosis and diagnosability analysis of DES modeled by Petri nets, depending on the boundedness properties of the net and on what is observable about its behavior. Let N be the Petri net model of the system, which consists of a Petri net structure along with an initial marking of all places. If the transitions of N are labeled by events in a set E, some by observable events in E_o and some by unobservable events in E_{uo}, and if the contents of the Petri net places are not observed except for the initial marking of N, then we have a language-based diagnosis problem as considered so far in this entry, for language $\mathcal{L}(N)$ and for $E = E_o \cup E_{uo}$, with event of interest $d \in E_{uo}$. In this case, if the set of reachable states of the net is bounded, then we can use the reachability graph as an equivalent automaton model of the same system and build a diagnoser automaton as described earlier. It is also possible to encode diagnoser states into the original structure of net N by keeping track of all possible net markings following the observation of an event in E_o, appending the appropriate label ("N" or "Y") to each marking in the state estimate. This is reminiscent of the on-the-fly construction of the current state of the diagnoser automaton discussed earlier, except that the possible system states are directly listed as Petri net markings on the structure of N. Regarding diagnosability

analysis, it can be performed using the twin-automaton technique of the preceding section, from the reachability graph of N.

Another approach that is actively being pursued in current literature is to exploit the structure of the net model N for diagnosis and for diagnosability analysis, instead of working with the automaton model obtained from its reachability graph. In addition to potential computational gains from avoiding the explicit generation of the entire set of reachable states, this approach is motivated by the need to handle Petri nets whose sets of reachable states are infinite and in particular Petri nets that generate languages that are not regular and hence cannot be represented by finite-state automata. Moreover, in this approach, one can incorporate potential observability of token contents in the places of the Petri nets. We refer the interested reader to the relevant chapters in Campos et al. (2013) and Seatzu et al. (2013) for coverage of these topics.

Current and Future Directions

The basic methodologies described so far for diagnosis and diagnosability analysis have been extended in many different directions. We briefly discuss a few of these directions, which are active research areas. Detailed coverage of these topics is beyond the scope of this entry and is available in the references listed at the end.

Diagnosis of *timed models* of DES has been considered, for classes of timed automata and timed Petri nets, where the objective is to ensure that each occurrence of event d is detected within a bounded time delay. Diagnosis of *stochastic models* of DES has been considered, in particular stochastic automata, where the hard diagnosability constraints are relaxed and detection of each occurrence of event d must be guaranteed with some probability $1 - \epsilon$, for some small $\epsilon > 0$. Stochastic models also allow handling of unreliable sensors or noisy environments where event observations may be corrupted with some probability, such as when an occurrence of event a is observed as event a 80 % of the time and as some other event a' 20 % of the time.

Decentralized diagnosis is concerned with DES that are observed by several monitoring agents $i = 1, \ldots, n$, each with its own set of observable events $E_{o,i}$ and each having access to the entire set of system behaviors, L_M. The task is to design a set of individual diagnosers, one for each set $E_{o,i}$, such that the n diagnosers together diagnose all the occurrences of event d. In other words, for each occurrence of event d in any string of L_M, there exists at least one diagnoser that will detect it (i.e., answer "Yes"). The individual diagnosers may or may not communicate with each other at run-time or they may communicate with a coordinating diagnoser that will fuse their information; several decentralized diagnosis architectures have been studied and their properties characterized. The focus in these works is the decentralized nature of the information available about the strings in L_M, as captured by the individual observable event sets $E_{o,i}$, $i = 1, \ldots, n$.

Distributed diagnosis is closely related to decentralized diagnosis, except that it normally refers to situations where each individual diagnoser uses only part of the entire system model. Let M be an automaton G obtained by parallel composition of subsystem models: $G = \|_{i=1,n} G_i$. In distributed diagnosis, one would want to design each individual diagnoser Diag_i on the basis of G_i alone or on the basis of G_i and of an *abstraction* of the rest of the system, $\|_{j=1,n; j \neq i} G_j$. Here, the emphasis is on the distributed nature of the system, as captured by the parallel composition operation. In the case where M is a Petri net N, the distributed nature of the system may be captured by individual net models N_i, $i = 1, \ldots, n$, that are coupled by common places, i.e., *place-bordered* Petri nets.

Robust diagnosis generally refers to decentralized or distributed diagnosis, but where one or more of the individual diagnosers may fail. Thus, there must be built-in redundancy in the set of individual diagnosers so that they together may still detect every occurrence of event d even if one or more of them ceases to operate.

So far we have considered a fixed and static set of observable events, $E_o \subset E$, where every occurrence of each event in E_o is always observed by the monitoring agent. However, there are many instances where one would want the monitoring agent to dynamically activate or de-activate the observability properties of a subset of the events in E_o; this arises in situations where event monitoring is "costly" in terms of energy, bandwidth, or security reasons. This is referred to as the case of *dynamic observations*, and the goal is to synthesize sensor activation policies that minimize a given cost function while preserving the diagnosability properties of the system.

Recommended Reading

There is a very large amount of literature on diagnosis and diagnosability analysis of DES that has been published in control engineering, computer science, and artificial intelligence journals and conference proceedings. We mention a few recent books or survey articles that are a good starting point for readers interested in learning more about this active area of research. In the DES literature, the study of fault diagnosis and the formalization of diagnosability properties started in Lin (1994) and Sampath et al. (1995). Chapter 2 of the textbook Cassandras and Lafortune (2008) contains basic results about diagnoser automata and diagnosability analysis of DES, following the approach introduced in Sampath et al. (1995). The research monograph Lamperti and Zanella (2003) presents DES diagnostic methodologies developed in the artificial intelligence literature. The survey paper Zaytoon and Lafortune (2013) presents a detailed overview of fault diagnosis research in the control engineering literature. The two edited books

Campos et al. (2013) and Seatzu et al. (2013) contain chapters specifically devoted to diagnosis of automata and Petri nets, with an emphasis on automated manufacturing applications for the latter. Specifically, Chaps. 5, 14, 15, 17, and 19 in Campos et al. (2013) and Chaps. 22–25 in Seatzu et al. (2013) are recommended for further reading on several aspects of DES diagnosis. Zaytoon and Lafortune (2013) and the cited chapters in Campos et al. (2013) and Seatzu et al. (2013) contain extensive bibliographies.

Differential Geometric Methods in Nonlinear Control

A.J. Krener
Department of Applied Mathematics, Naval Postgrauate School, Monterey, CA, USA

Abstract

In the early 1970s, concepts from differential geometry were introduced to study nonlinear control systems. The leading researchers in this effort were Roger Brockett, Robert Hermann, Henry Hermes, Alberto Isidori, Velimir Jurdjevic, Arthur Krener, Claude Lobry, and Hector Sussmann. These concepts revolutionized our knowledge of the analytic properties of control systems, e.g., controllability, observability, minimality, and decoupling. With these concepts, a theory of nonlinear control systems emerged that generalized the linear theory. This theory of nonlinear systems is largely parallel to the linear theory, but of course it is considerably more complicated.

Keywords

Introduction

This is a brief survey of the influence of differential geometric concepts on the development of nonlinear systems theory. Section "A Primer on Differential Geometry" reviews some concepts and theorems of differential geometry. Nonlinear controllability and nonlinear observability are discussed in sections "Controllability of Nonlinear Systems" and "Observability for Nonlinear Systems". Section "Minimal Realizations" discusses minimal realizations of nonlinear systems, and section "Disturbance Decoupling" discusses the disturbance decoupling problem.

A Primer on Differential Geometry

Perhaps a better title might be "A Primer on Differential Topology" since we will not treat Riemannian or other metrics. A n-dimensional manifold $\mathcal{M}$ is a topological space that is locally homeomorphic to a subset of IR^n. For simplicity, we shall restrict our attention to smooth (C^∞) manifolds and smooth objects on them. Around each point $p \in \mathcal{M}$, there is at least one coordinate chart that is a neighborhood $\mathcal{N}_p \subset \mathcal{M}$ and a homeomorphism $x : \mathcal{N}_p \rightarrow \mathcal{U}$ where $\mathcal{U}$ is an open subset of IR^n. When two coordinate

D

charts overlap, the change of coordinates should be smooth. For simplicity, we restrict our attention to differential geometric objects described in local coordinates.

In local coordinates, a vector field is just an ODE of the form

$$\dot{x} = f(x) \tag{1}$$

where $f(x)$ is a smooth $IR^{n \times 1}$ valued function of x. In a different coordinate chart with local coordinates z, this vector field would be represented by a different formula:

$$\dot{z} = g(z)$$

If the charts overlap, then on the overlap they are related:

$$f(x(z)) = \frac{\partial x}{\partial z}(z)g(z), \ \ g(z(x)) = \frac{\partial z}{\partial x}(z)f(x)$$

Since $f(x)$ is smooth, it generates a smooth flow $\phi(t, x^0)$ where for each t, the mapping $x \mapsto \phi(t, x^0)$ is a local diffeomorphism and for each x^0 the mapping $t \mapsto \phi(t, x^0)$ is a solution of the ODE (1) satisfying the initial condition $\phi(0, x^0) = x^0$. We assume that all the flows are complete, i.e., defined for all $t \in IR$, $x \in \mathcal{M}$. The flows are one parameter groups, i.e., $\phi(t, \phi(s, x^0)) = \phi(t + s, x^0) = \phi(s, \phi(t, x^0))$.

If $f(x^0) = b$, a constant vector, then locally the flow looks like translation, $\phi(t, x^1) = x^1 + tb$. If $f(x^0) \neq 0$, then we can always choose local coordinates z so that in these coordinates the vector field is constant. Without loss of generality, we can assume that $x^0 = 0$ and that the first component of f is $f_1(0) \neq 0$. Define the local change of coordinates: $x(z) = \phi(z_1, x^1(z))$ where $x^1(z) = (0, z_2, \ldots, z_n)'$. It is not hard to that this is a local diffeomorphism and that, in z coordinates, the vector field is the first unit vector.

If $f(x^0) = 0$ let $F = \frac{\partial f}{\partial x}(x^0)$, then if all the eigenvalues of F are off the imaginary axis, then the integral curves of $f(x)$ and

$$\dot{z} = Fz \tag{2}$$

are locally topologically equivalent (Arnol'd 1983). This is the Grobman-Hartman theorem. There exists a local homeomorphism $z = h(x)$ that carries $x(t)$ trajectories into $z(s)$ trajectories in some neighborhood of $x^0 = 0$. This homeomorphism need not preserve time $t \neq s$, but it does preserve the direction of time. Whether these flows are locally diffeomorphic is a more difficult question that was explored by Poincaré. See the section on feedback linearization (Krener 2013).

If all the eigenvalues of F are in the open left half plane, then the linear dynamics (2) is globally asymptotically stable around $z^0 = 0$, i.e., if the flow of (2) is $\psi(t, z)$, then $\psi(t, z^1) \to 0$ as $t \to \infty$. Then it can be shown that the nonlinear dynamics is locally asymptotically stable, $\phi(t, x^1) \to x^0$ as $t \to \infty$ for all x^1 in some neighborhood of x^0.

One forms, $\omega(x)$, are dual to vector fields. The simplest example of a one form (also called a covector field) is the differential $dh(x)$ of a scalar-valued smooth function $h(x)$. This is the $IR^{1 \times n}$ covector field

$$\omega(x) = \left[\ \frac{\partial h}{\partial x_1}(x) \ \ldots \ \frac{\partial h}{\partial x_n}(x) \ \right]$$

Sometimes this is written as

$$\omega(x) = \sum_1^n \frac{\partial h}{\partial x_i}(x) \, dx_i$$

The most general smooth one form is of the form

$$\omega(x) = \left[\ \omega^1(x) \ \ldots \ \omega^n(x) \ \right]$$
$$= \sum_{i=1}^n \omega^i(x) \, dx_i$$

where the $\omega^i(x)$ are smooth functions. The duality between one forms and vector fields is the bilinear pairing

$$< \omega(x), f(x) > = \omega(f)(x) = \omega(x)f(x)$$
$$= \sum_{i=1}^n \omega^i(x) f_i(x)$$

Just as a vector field can be thought of as a first-order ODE, a one form can be thought of as a first-order PDE. Given $\omega(x)$, find $h(x)$ such that $dh(x) = \omega(x)$. A one form $\omega(x)$ is said to be exact if there exists such an $h(x)$. Of course if there is one solution, then there are many all differing by a constant of integration which we can take as the value of h at some point x^0.

Unlike smooth first-order ODEs, smooth first-order PDEs do not always have a solution. There are integrability conditions and topological conditions that must be satisfied. Suppose $dh(x) = \omega(x)$, then $\frac{\partial h}{\partial x_i}(x) = \omega^i(x)$ so

$$\frac{\partial \omega^i}{\partial x_j}(x) = \frac{\partial^2 h}{\partial x_j \partial x_i}(x) = \frac{\partial^2 h}{\partial x_i \partial x_j}(x) = \frac{\partial \omega^j}{\partial x_i}(x)$$

Therefore, for the PDE to have a solution, the integrability conditions

$$\frac{\partial \omega^i}{\partial x_j}(x) - \frac{\partial \omega^j}{\partial x_i}(x) = 0$$

must be satisfied. The exterior derivative of a one form is a skew-symmetric matrix field

$$d\omega(x) = \sum_{i<j} \left(\frac{\partial \omega^i}{\partial x_j}(x) - \frac{\partial \omega^j}{\partial x_i}(x) \right) dx_i \wedge dx_j$$

A one form $\omega(x)$ is said to be closed if $d\omega(x) = 0$. This is locally sufficient for there to exist an $h(x)$ such that $dh(x) = \omega(x)$.

Every exact form is closed but not every closed form is exact. A counter example on IR^2 is

$$\omega(x) = \begin{bmatrix} -x_2 & x_1 \end{bmatrix}$$

This is closed but not exact. The line integral of this convector field around any circle centered at the origin is 2π. If it were exact, the line integral would have been zero because the curve ends where it begins.

The Lie derivative of a scalar-valued function $h(x)$ by a vector field $f(x)$ is denied to be the scalar-valued function

$$L_f(h)(x) = \frac{\partial h}{\partial x}(x) f(x) = \; <dh(x), f(x)>$$

This can be iterated

$$L_f^k(h)(x) = \frac{\partial L_f^{k-1}h}{\partial x}(x) f(x)$$

If $h(x) \in IR^{p\times 1}$, then $L_f(h)(x) \in IR^{p\times 1}$.

The Lie bracket of two vector fields $f^1(x)$ and $f^2(x)$ is another vector field

$$\left[f^1, f^2\right](x) = \frac{\partial f^2}{\partial x}(x) f^1(x) - \frac{\partial f^1}{\partial x}(x) f^2(x)$$

Clearly, the Lie bracket is skew symmetric, $\left[f^1, f^2\right](x) = -\left[f^2, f^1\right](x)(x)$. It also satisfies the Jacobi identity

$$\left[f^1, \left[f^2, f^3\right]\right](x) + \left[f^2, \left[f^3, f^1\right]\right](x)$$
$$+ \left[f^3, \left[f^1, f^2\right]\right](x) = 0$$

Repeated Lie brackets are often expressed inductively as

$$ad_f^0(g)(x) = g(x)$$
$$ad_f^k(g)(x) = \left[f, ad_f^{k-1}(g)\right](x)$$

The geometric interpretation of the Lie bracket $[f, g](x)$ is the infinitesimal commutator of their flows $\phi(t, x)$ and $\psi(t, x)$, i.e.,

$$\psi(t, \phi(t, x)) - \phi(t, \psi(t, x)) = [f, g](x) t^2$$
$$+ O(t)^3$$

Another interpretation of the Lie bracket is given by the Lie series expansion

$$g(\phi(t, x)) = \sum_{k=0}^{\infty} (-1)^k ad_f^k(g)(x) \frac{t^k}{k!}$$

This is a Taylor series expansion which is convergent for small $|t|$ if f, g are real analytic vector fields. Another Lie series is

$$h(\phi(t, x)) = \sum_{k=0}^{\infty} L_f^k(h)(x) \frac{t^k}{k!}$$

Given a smooth mapping $z = \theta(x)$ from an open subset of IR^n to an open subset of IR^m and vector fields $f(x)$ and $g(z)$ on these open subsets, we sat $f(x)$ is θ-related to $g(z)$ if

$$g(\theta(x)) = \frac{\partial \theta}{\partial x}(x) f(x)$$

It is not hard to see that if $f^1(x)$, $f^2(x)$ are θ-related to $g^1(z)$, $g^2(z)$, then $\left[f^1, f^2\right](x)$ is θ-related to $\left[g^1, g^2\right](z)$. For this reason, we say that the Lie bracket is an intrinsic differentiation. The other intrinsic differentiation is the exterior derivative operation d.

The Lie derivative of a one form $\omega(x)$ by a vector field $f(x)$ is given by

$$L_f(\omega)(x) = \sum_{i,j} \left(\frac{\partial \omega^i}{\partial x_j}(x) f_j(x) \right.$$
$$\left. + \omega_j(x) \frac{\partial f_j}{\partial x_i}(x) \right) \, dx_i$$

It is not hard to see that

$$L_f(<\omega, g>)(x) = <L_f(\omega), g>(x)$$
$$+ <\omega, [f, g]>(x)$$

and

$$L_f(dh)(x) = d(L_f(h))(x) \qquad (3)$$

Control systems involve multiple vector fields. A distribution $\mathcal{D}$ is a set of vector fields on $\mathcal{M}$ that is closed under addition of vector fields and under multiplication by scalar functions. A distribution defines at each $x \in \mathcal{M}$ a subspace of the tangent space

$$D(x) = \{f(x) : f \in \mathcal{D}\}$$

These subspaces form a subbundle D of the tangent bundle. If the subspaces are all of the same dimension, then the distribution is said to be nonsingular. We will restrict our attention to nonsingular distributions.

A codistribution (or Pfaffian system) $\mathcal{E}$ is a set of one forms on $\mathcal{M}$ that is closed under addition and multiplication by scalar functions.

A codistribution defines at each $x \in \mathcal{M}$ a subspace of the cotangent space

$$\{\omega(x) : \omega \in \mathcal{E}\}$$

These subspaces form a subbundle E of the cotangent bundle. If the subspaces are all of the same dimension, then the codistribution is said to be nonsingular. Again, we will restrict our attention to nonsingular codistributions.

Every distribution $\mathcal{D}$ defines a dual codistribution

$$\mathcal{D}^* = \{\omega(x) : \omega(x) f(x) = 0, \text{ for all } f(x) \in \mathcal{D}\}$$

and vice versa

$$\mathcal{E}_* = \{f(x) : \omega(x) f(x) = 0, \text{ for all } \omega(x) \in \mathcal{E}\}$$

A k dimensional distribution $\mathcal{D}$ (or its dual codistribution $\mathcal{D}^*$) can be thought of as a system of PDEs on $\mathcal{M}$. Find $n-k$ independent functions $h_1(x), \ldots, h_{n-k}(x)$ such that

$$dh_i(x) f(x) = 0 \text{ for all } f(x) \in \mathcal{D}$$

The functions $h_1(x), \ldots, h_{n-k}(x)$ are said to be independent if $dh_1(x), \ldots, dh_{n-k}(x)$ are linearly independent at every $x \in \mathcal{M}$. In other words, $dh_1(x), \ldots, dh_{n-k}(x)$ span $\mathcal{D}^*$ over the space of smooth functions.

The Frobenius theorem gives the integrability conditions for these functions to exist locally. The distribution $\mathcal{D}$ must be involutive, i.e., closed under the Lie bracket,

$$[\mathcal{D}, \mathcal{D}] = \{[f, g] : f, g \in \mathcal{D}\} \subset \mathcal{D}$$

When the functions exist, their joint level sets $\{x : h_i(x) = c_i, i = 1, \ldots, n - k\}$ are the leaves of a local foliation. Through each x^0 in a convex local coordinate chart $\mathcal{N}$, there exists locally a a k-dimensional submanifold $\{x \in \mathcal{N} : h_i(x) = h_i(x^0)\}$. At each x^1 in this submanifold, its tangent space is $D(x)$. Whether these $h_i(x)$ exist globally to define a global foliation, a partition of $\mathcal{M}$ into smooth submanifolds, is a delicate question. Consider a distribution on IR^2 generated by a constant vector field $f(x) = b$

of irrational slope, b_2/b_1 is irrational. Construct the torus T^2 as the quotient of IR^2 by the integer lattice Z^2. The distribution passes to the quotient and since it is one dimensional, it is clearly involutive. The leaves of the quotient distribution are curves that wind around the torus indefinitely, and each curve is dense in T^2. Therefore, any smooth function $h(x)$ that is constant on such a leaf is constant on all of T^2. Hence, the local foliation does not extend to a global foliation.

Another delicate question is whether the quotient space of $\mathcal{M}$ by a foliation induced by an involutive distribution is a smooth manifold (Sussmann 1975). This is always true locally, but it may not hold globally. Think of the foliation of T^2 discussed above.

Given $k \leq n$ vector fields $f^1(x), \ldots, f^k(x)$ that are linearly independent at each x and that commute, $\left[f^i, f^j\right](x) = 0$, there exists a local change of coordinates $z = z(x)$ so that in the new coordinates the vector fields are the first k unit vectors.

The involutive closure $\bar{\mathcal{D}}$ of $\mathcal{D}$ is the smallest involutive distribution containing $\mathcal{D}$. As with all distributions, we always assume implicitly that is nonsingular. A point x^1 is $\mathcal{D}$-accessible from x^0 if there exists a continuous and piecewise smooth curve joining x^0 to x^1 whose left and right tangent vectors are always in D. Obviously $\mathcal{D}$-accessibility is an equivalence relation. Chow's theorem (1939) asserts that its equivalence classes are the leaves of the foliation induced by $\bar{\mathcal{D}}$. Chow's theorem goes a step further. Suppose $f^1(x), \ldots, f^k(x)$ span $D(x)$ at each $x \in \mathcal{M}$ then given any two points x^0, x^1 in a leaf of $\bar{\mathcal{D}}$, there is a continuous and piecewise smooth curve joining x^0 to x^1 whose left and right tangent vectors are always one of the $f^i(x)$.

Controllability of Nonlinear Systems

An initialized nonlinear system that is affine in the control is of the form

$$
\begin{aligned}
\dot{x} &= f(x) + g(x)u \\
&= f(x) + \sum_{j=1}^{m} g^j(x)u_j \\
y &= h(x) \\
x(0) &= x^0
\end{aligned}
\tag{4}
$$

where the state x are local coordinates on an n-dimensional manifold $\mathcal{M}$, the control u is restricted to lie in some set $\mathcal{U} \subset IR^m$, and the output y takes values IR^p. We shall only consider such systems.

A particular case is a linear system of the form

$$
\begin{aligned}
\dot{x} &= Fx + Gu \\
y &= Hx \\
x(0) &= x^0
\end{aligned}
\tag{5}
$$

where $\mathcal{M} = IR^n$ and $\mathcal{U} = IR^m$.

The set $\mathcal{A}_t(x^0)$ of points accessible at time $t \geq 0$ from x^0 is the set of all $x^1 \in \mathcal{M}$ such that there exists a bounded, measurable control trajectory $u(s) \in \mathcal{U}$, $0 \leq s \leq t$, so that the solution of (4) satisfies $x(t) = x^1$. We define $\mathcal{A}(x^0)$ as the union of $\mathcal{A}_t(x^0)$ for all $t \geq 0$. The system (4) is said to be controllable at time $t > 0$ if $\mathcal{A}_t(x^0) = \mathcal{M}$ and controllable in forward time if $\mathcal{A}(x^0) = \mathcal{M}$.

For linear systems, controllability is a rather straightforward matter, but for nonlinear systems it is more subtle with numerous variations. The variation of constants formula gives the solution of the linear system (5) as

$$
x(t) = e^{Ft}x^0 + \int_0^t e^{F(t-s)}Gu(s)\,ds
$$

so $\mathcal{A}_t(x^0)$ is an affine subspace of IR^n for any $t > 0$. It is not hard to see that the columns of

$$
\left[\, G \ldots F^{n-1}G \,\right]
\tag{6}
$$

are tangent to this affine subspace, so if this matrix is of rank n, then $\mathcal{A}_t(x^0) = IR^n$ for any $t > 0$. This is the so-called controllability rank condition for linear systems.

Turning to the nonlinear system (4), let $\mathcal{D}$ be the distribution spanned by the vector fields $f(x), g^1(x), \ldots, g^m(x)$, and let $\bar{\mathcal{D}}$ be its involutive closure. It is clear that $\mathcal{A}(x^0)$ is contained in the leaf of $\bar{\mathcal{D}}$ through x^0. Krener (1971) showed that $\mathcal{A}(x^0)$ has nonempty interior in this leaf. More precisely, $\mathcal{A}(x^0)$ is between an open set and its closure in the relative topology of the leaf.

D

Let $\mathcal{D}_0$ be the smallest distribution containing the vector fields $g^1(x), \ldots, g^m(x)$ and invariant under bracketing by $f(x)$, i.e.,

$$[f, \mathcal{D}_0] \subset \mathcal{D}_0$$

and let $\bar{\mathcal{D}}_0$ be its involutive closure. Sussmann and Jurdjevic (1972) showed that $\mathcal{A}_t(x^0)$ is in the leaf of $\bar{\mathcal{D}}_0$ through x^0, and it is between an open set and its closure in the topology of this leaf.

For linear systems (5) where $f(x) = Fx$ and $g^j(x) = G^j$, the jth column of G, it is not hard to see that

$$ad_f^k(g^j)(x) = (-1)^k F^k G^j$$

so the nonlinear generalization of the controllability rank condition is that at each x the dimension of $\bar{D}_0(x)$ is n. This guarantees that $\mathcal{A}_t(x^0)$ is between an open set and its closure in the topology of $\mathcal{M}$.

The condition that

$$\text{dimension } \bar{D}(x) = n \tag{7}$$

is referred to as the nonlinear controllability rank condition. This guarantees that $\mathcal{A}(x^0)$ is between an open set and its closure in the topology of $\mathcal{M}$.

There are stronger interpretations of controllability for nonlinear systems. One is short time local controllability (STLC). The definition of this is that the set of accessible points from x^0 in any small $t > 0$ with state trajectories restricted to an arbitrarily small neighborhood of x^0 should contain x^0 in its interior. Hermes (1994) and others have done work on this.

Observability for Nonlinear Systems

Two possible initial states x^0, x^1 for the nonlinear system are distinguishable if there exists a control $u(\cdot)$ such that the corresponding outputs $y^0(t)$, $y^1(t)$ are not equal. They are short time distinguishable if there is an $u(\cdot)$ such that $y^0(t) \neq y^1(t)$ for all small $t > 0$. They are locally short time distinguishable if in addition the corresponding state trajectories do not leave an

arbitrarily small open set containing x^0, x^1. The open set need not be connected. A nonlinear system is (short time, locally short time) observable if every pair of initial states is (short time, locally short time) distinguishable. Finally, a nonlinear system is (short time, locally short time) locally observable if every x^0 has a neighborhood such that every other point x^1 in the neighborhood is (short time, locally short time) distinguishable from x^0.

For a linear system (5), all these definitions coalesce into a single concept of observability which can be checked by the observability rank condition which is that the rank of

$$\begin{bmatrix} H \\ HF \\ \vdots \\ HF^{n-1} \end{bmatrix} \tag{8}$$

equals n.

The corresponding concept for nonlinear systems involves $\mathcal{E}$, the smallest codistribution containing $dh_1(x), \ldots, dh_p(x)$ that is invariant under repeated Lie differentiation by the vector fields $f(x), g^1(x), \ldots, g^m(x)$. Let

$$E(x) = \{\omega(x) : \omega \in \mathcal{E}\}$$

The nonlinear observability rank condition is

$$\text{dimension } E(x) = n \tag{9}$$

for all $x \in \mathcal{M}$. This condition guarantees that the nonlinear system is locally short time, locally observable. It follows from (3) that $\mathcal{E}$ is spanned by a set of exact one form, so its dual distribution $\mathcal{E}^*$ is involutive.

For a linear system (5), the input–output mapping from $x(0) = x^i, i = 0, 1$ is

$$y^i(t) = He^{Ft}x^i + \int_0^t He^{F(t-s)}Gu(s)\, ds$$

The difference is

$$y1(t) - y^0(t) = He^{Ft}(x^1 - x^0)$$

So if one input $u(\cdot)$ distinguishes x^0 from x^1, then so does every input.

For nonlinear systems, this is not necessarily true. That prompted Gauthier et al. (1992) to introduce a stronger concept of observability for nonlinear systems. For simplicity, we describe it for scalar input and scalar output systems. A nonlinear system is uniformly observable for any input if there exist local coordinates so that it is of the form

$$y = x_1 + h(u)$$
$$\dot{x}_1 = x_2 + f_1(x_1, u)$$
$$\vdots$$
$$\dot{x}_{n-1} = x_n + f_{n-1}(x_1, \ldots, x_{n-2}, u)$$
$$\dot{x}_n = f_n(x, u)$$

Cleary if we know $u(\cdot)$, $y(\cdot)$, then by repeated differentiation of $y(\cdot)$, we can reconstruct $x(\cdot)$. It has been shown that for nonlinear systems that are uniformly observable for any input, the extended Kalman filter is a locally convergent observer (Krener 2002a), and the minimum energy estimator is globally convergent (Krener 2002b).

Minimal Realizations

The initialized nonlinear system (4) can be viewed as defining a input–output mapping from input trajectories $u(\cdot)$ to output trajectories $y(\cdot)$. Is it a minimal realization of this mapping, does there exists an initialized nonlinear system on a smaller dimensional state space that realizes the same input–output mapping?

Kalman showed that (5) initialized at $x^0 = 0$ is minimal iff the controllability rank condition and the observability rank condition hold. He also showed how to reduce a linear system to a minimal one.

If the controllability rank condition does not hold, then the span of (6) dimension is $k < n$. This subspace contains the columns of G and is invariant under multiplication by F. In fact, it is the maximal subspace with these properties. So the linear system can be restricted to

this k-dimensional subspace, and it realizes the same input–output mapping from $x^0 = 0$. The restricted system satisfies the controllability rank condition.

If the observability rank condition does not hold, then the kernel of (8) is a subspace of $\mathit{IR}^{n\times 1}$ of dimension $n - l > 0$. This subspace is in the kernel of H and is invariant under multiplication by F. In fact, it is the maximal subspace with these properties. Therefore, there is a quotient linear system on the $\mathit{IR}^{n\times 1}$ mod, the kernel of (8) which has the same input–output mapping. The quotient is of dimension $l < n$, and it realizes the same input–output mapping. The quotient system satisfies the observability rank condition.

By employing these two steps in either order, we pass to a minimal realization of the input–output map of (5) from $x^0 = 0$. Kalman also showed that two linear minimal realizations differ by a linear change of state coordinates.

An initialized nonlinear system is a realization of minimal dimension of its input–output mapping if the nonlinear controllability rank condition (7) and the nonlinear observability rank condition (9) hold.

If the nonlinear controllability rank condition (7) fails to hold because the dimension of $D(x)$ is $k < n$, then by replacing the state space $\mathcal{M}$ with the k dimensional leaf through x^0 of the foliation induced by $\mathcal{D}$, we obtain a smaller state space on which the nonlinear controllability rank condition (7) holds. The input–output mapping is unchanged by this restriction.

Suppose the nonlinear observability rank condition (9) fails to hold because the dimension of $E(x)$ is $l < n$. Then consider a convex neighborhood $\mathcal{N}$ of x^0. The distribution $\mathcal{E}^*$ induces a local foliation of $\mathcal{N}$ into leaves of dimension $n - l > 0$. The nonlinear system leaves this local foliation invariant in the following sense. Suppose x^0 and x^1 are on the same leaf then if $x^i(t)$ is the trajectory starting at x^i, then $x^0(t)$ and $x^1(t)$ are on the same leaf as long as the trajectories remain in $\mathcal{N}$. Furthermore, $h(x)$ is constant on leaves so $y^0(t) = y^1(t)$. Hence, there exists locally a nonlinear system whose state space is the leaf space. On this leaf space, the nonlinear observability rank condition holds (9),

and the projected system has the same input–output map as the original locally around x^0. If the leaf space of the foliation induced by $\mathcal{E}^*$ admits the structure of a manifold, then the reduced system can be defined globally on it. Sussmann (1973) and Sussmann (1977) studied minimal realizations of analytic nonlinear systems.

The state space of two minimal nonlinear systems need not be diffeomorphic. Consider the system

$$\dot{x} = u, \;\; y = \sin x$$

where x, u are scalars. We can take the state space to be either $\mathcal{M} = I\!R$ or $\mathcal{M} = S^1$, and we will realize the same input–output mapping. These two state spaces are certainly not diffeomorphic but one is a covering space of the other.

Lie Jet and Approximations

Consider two initialized nonlinear controlled dynamics

$$\dot{x} = f^0(x) + \sum_{j=1}^m f^j(x)u_j \quad (10)$$
$$x(0) = x^0$$

$$\dot{z} = g^0(z) + \sum_{j=1}^m g^j(z)u_j \quad (11)$$
$$z(0) = z^0$$

Suppose that (10) satisfies the nonlinear controllability rank condition (7). Further, suppose that there is a smooth mapping $\Phi(x) = z$ and constants $M > 0, \epsilon > 0$ such that for any $\|u(t)\| < 1$, the corresponding trajectories $x(t)$ and $z(t)$ satisfy

$$\|\Phi(x(t)) - z(t)\| < Mt^{k+1} \quad (12)$$

for $0 \le t < \epsilon$.

Then it is not hard to show that the linear map $L = \frac{\partial \Phi}{\partial x}(x^0)$ takes brackets up to order k of the vector fields f^j evaluated at x^0 into the corresponding brackets of the vector fields g^j evaluated at z^0,

$$L[f^{j_l}[\ldots[f^{j_2}, f^{j_1}]\ldots]](x^0)$$
$$= [g^{j_l}[\ldots[g^{j_2}, g^{j_1}]\ldots]](z^0) \quad (13)$$

for $1 \le l \le k$.

On the other hand, if there is a linear map L such that (13) holds for $1 \le l \le k$, then there exists a smooth mapping $\Phi(x) = z$ and constants $M > 0, \epsilon > 0$ such that for any $\|u(t)\| < 1$, the corresponding trajectories $x(t)$ and $z(t)$ satisfy (12).

The k-Lie jet of (10) at x^0 is the tree of brackets $[f^{j_l}[\ldots[f^{j_2}, f^{j_1}]\ldots]](x^0)$ for $1 \le l \le k$. In some sense these are the coordinate-free Taylor series coefficients of (10) at x^0.

The dynamics (10) is free-nilpotent of degree k if all these brackets are as linearly independent as possible consistent with skew symmetry and the Jacobi identity and all higher degree brackets are zero. If it is free to degree k, the controlled dynamics (10) can be used to approximate any other controlled dynamics (11) to degree k. Because it is nilpotent, integrating (10) reduces to repeated quadratures. If all brackets with two or more f^i, $1 \le i \le m$ are zero at x^0, then (10) is linear in appropriate coordinates. If all brackets with three or more f^i, $1 \le i \le m$ are zero at x^0, then (10) is quadratic in appropriate coordinates. The references Krener and Schaettler (1988) and Krener (2010a,b) discuss the structure of the reachable sets for such systems.

Disturbance Decoupling

Consider a control system affected by a disturbance input $w(t)$

$$\dot{x} = f(x) + g(x)u + b(x)w$$
$$y = h(x) \quad (14)$$

The disturbance decoupling problem is to find a feedback $u = \kappa(x)$, so that in the closed-loop system, the output $y(t)$ is not affected by the disturbance $w(t)$. Wonham and Morse (1970) solved this problem for a linear system

$$\dot{x} = Fx + Gu + Bw$$
$$y = Hx \quad (15)$$

To do so, they introduced the concept of an F, G invariant subspace. A subspace $\mathcal{V} \subset IR^n$ is F, G invariant if

$$F\mathcal{V} \subset \mathcal{V} + \mathcal{G} \qquad (16)$$

where $\mathcal{G}$ is the span of the columns of G. It is easy to see that $\mathcal{V}$ is F, G invariant iff there exists a $K \in IR^{m \times n}$ such that

$$(F + GK)\mathcal{V} \subset \mathcal{V} \qquad (17)$$

The feedback gain K is called a friend of $\mathcal{V}$.

It is easy from (16) that if $\mathcal{V}^i$ is F, G invariant for $i = 1, 2$, then $\mathcal{V}^1 + \mathcal{V}^2$ is also. So there exists a maximal F, G invariant subspace $\mathcal{V}^{\max}$ in the kernel of H. Wonham and Morse showed that the linear disturbance decoupling problem is solvable iff $\mathcal{B} \subset \mathcal{V}^{\max}$ where $\mathcal{B}$ is the span of the columns of B.

Isidori et al. (1981a) and independently Hirschorn (1981) solved the nonlinear disturbance decoupling problem. A distribution $\mathcal{D}$ is locally f, g invariant if

$$\begin{aligned} [f, \mathcal{D}] &\subset \mathcal{D} + \Gamma \\ [g^j, \mathcal{D}] &\subset \mathcal{D} + \Gamma \end{aligned} \qquad (18)$$

for $j = 1, \ldots, m$ where Γ is the distribution spanned by the columns of g. In Isidori et al. (1981b) it is shown that if $\mathcal{D}$ is locally f, g invariant, then so is its involutive closure.

A distribution $\mathcal{D}$ is f, g invariant if there exists $\alpha(x) \in IR^{m \times 1}$ and invertible $\beta(x) \in IR^{m \times m}$ such that

$$\begin{aligned} [f + g\alpha, \mathcal{D}] &\subset \mathcal{D} \\ \left[\sum_j g^j \beta_j^k, \mathcal{D}\right] &\subset \mathcal{D} \end{aligned} \qquad (19)$$

for $k = 1, \ldots, m$. It is not hard to see that a f, g invariant is locally f, g invariant. It is shown in Isidori et al. (1981b) that if $\mathcal{D}$ is a locally f, g invariant distribution, then locally there exists $\alpha(x)$ and $\beta(x)$ so that (19) holds. Furthermore, if the state space is simply connected, then $\alpha(x)$ and $\beta(x)$ exist globally, but the matrix field $\beta(x)$ may fail to be invertible at some x.

From (18), it is clear that if $\mathcal{D}^i$ is locally f, g invariant for $i = 1, 2$, then so is $\mathcal{D}^1 + \mathcal{D}^2$. Hence, there exists a maximal locally f, g invariant

distribution $\mathcal{D}^{\max}$ in the kernel of dh. Moreover, this distribution is involutive. The disturbance decoupling problem is locally solvable iff columns of $b(x)$ are contained in $\mathcal{D}^{\max}$. If $\mathcal{M}$ is simply connected, then the disturbance decoupling problem is globally solvable iff columns of $b(x)$ are contained in $\mathcal{D}^{\max}$.

Conclusion

We have briefly described the role that differential geometric concepts played in the development of controllability, observability, minimality, approximation, and decoupling of nonlinear systems.

Disaster Response Robot

Satoshi Tadokoro
Tohoku University, Sendai, Japan

Abstract

Disaster response robots are robotic systems used for preventing the worsening of disaster damage under emergent situations. Robots for natural disasters (water disaster, volcano eruption, earthquakes, landslides, and fire) and man-made disasters (explosive ordnance disposal, CBRNE disasters, Fukushima Daiichi nuclear power plant accident) are introduced. Technical challenges are described on the basis of generalized data flow.

Keywords

Rescue robot; Response robot

Introduction

Disaster response robots are robotic systems used for preventing the worsening of disaster damage under emergent situations, such as for search and rescue, recovery construction, etc.

A disaster changes its state as time passes. The state starts as an unforeseen occurrence and proceeds to prevention phase, emergency response phase, recovery phase, and revival phase. Although a disaster response robot usually means a system for disaster response and recovery in a narrow sense a system used in every phase of disaster can be called a disaster response robot in a broad sense.

When parties of firefighters and military personnel respond to disasters, robots are among the technical equipments used. The purposes of robots are (1) to perform tasks that are impossible/difficult to perform by humans and conventional equipment, (2) to reduce responders' risk of inflicting secondary damage, and (3) to improve rapidity/efficiency of tasks, by using remote/automatic robot equipment.

Response Robots for Natural Disasters

Water Disaster

Underwater robots (ROV, remotely operated vehicle) are deployed to responder organizations in preparation for water damage such as caused by tsunami, flood, cataract, and accidents in the sea and rivers. They are equipped with cameras and sonars and remotely controlled by crews via tether from land or shipboard within several tens of meters area for victim search and damage investigation. After the Great Eastern Japan Earthquake in 2011, Self Defense Force and volunteers of International Rescue System Institute (IRS) and Center for Robot-Assisted Search and Rescue (CRASAR) used various types of ROVs such as SARbot shown in Fig. 1 for victim search and debris investigation in the port.

Volcano Eruption

In order to reduce risk in monitoring and recovery construction at volcano eruptions, application of robotics and remote systems is highly desired. Various types of UAVs (unmanned aerial vehicles) such as small-sized robot helicopters and airplanes have been used for this purpose.

An unmanned construction system consists of teleoperated robot backhoes, trucks, and bulldozers with wireless relaying cars and camera vehicles as shown in Fig. 2 and is remotely controlled from an operator vehicle. It has been used since the 1990s for remote civil engineering works from a distance of a few kilometers.

Structural Collapse by Earthquakes, Landslides, etc.

Small-sized UGVs (unmanned ground vehicles) were developed for victim search and monitoring in confined spaces of collapsed buildings and underground structures. VGTV X-treme shown in Fig. 3 is a tracked vehicle remotely operated via a tether. It was used for victim search at mine accidents and the 9/11 terror attack. Active scope camera shown in Fig. 4 is a serpentine robot like a fiberscope and has been used for forensic investigation of structural collapse accidents.

Fire

Large-scale fires in chemical plants and forests sometimes have a high risk, and firefighters cannot approach near them. Remote-controlled robots with firefighting nozzles for water and chemical extinguishing agents are deployed.

Disaster Response Robot, Fig. 3 VGTV X-treme (Courtesy of Recce Robotics) http://www.recce-robotics.com/vgtv.html

Disaster Response Robot, Fig. 4 Active scope camera (Courtesy of International Rescue System Institute)

Large-sized robots can discharge large volumes of the fluid with water cannons, whereas small-sized robots have better mobility.

Response Robots for Man-Made Disasters

Explosive Ordnance Disposal (EOD)

Detection and disposal of explosive ordnance is one of the most dangerous tasks. TALON, PackBot, and Telemax are widely used in military and explosive ordnance disposal teams worldwide. Telemax has an arm with seven degrees of freedom on a tracked vehicle with four sub-tracks as shown in Fig. 5. It can observe narrow spaces like overhead lockers of airplanes and bottom of automobiles by cameras, manipulate objects by the arm, and deactivate explosives by a disrupter.

CBRNE Disasters

CBRNE (chemical, biological, radiological, nuclear, and explosive) disasters have a high risk and can cause large-scale damage because human cannot detect contamination by the Hazmat (hazardous materials). Application of robotic systems is highly expected for this disaster. PackBot has sensors for toxic industrial chemicals (TIC), blood agents, blister agents, volatile organic compounds (VOCs), radiation, etc., as options and can measure the Hazmat in dangerous confined spaces (Fig. 6). Quince was developed for research into technical issues of UGVs at CBRNE disasters and has high mobility on rough terrain (Fig. 7).

Fukushima Daiichi Nuclear Power Plant Accident

At the Fukushima Daiichi nuclear power plant accident caused by tsunami in 2011, various disaster response robots were applied. They contributed to the cool shutdown and decommissioning of the plant. For example, PackBot and Quince gave essential data for task planning by shooting images and radiation measurement in nuclear reactor buildings there. Unmanned construction system removed debris outdoors that were contaminated by radiological materials and reduced the radiation rate there significantly.

Group INTRA in France and KHG in Germany are organizations for responding to nuclear plant accidents. They are equipped with robots and remote-controlled construction machines for radiation measurement, decontamination, and constructions in emergency. In Japan, the Assist Center for Nuclear Emergencies was established after the Fukushima Accident.

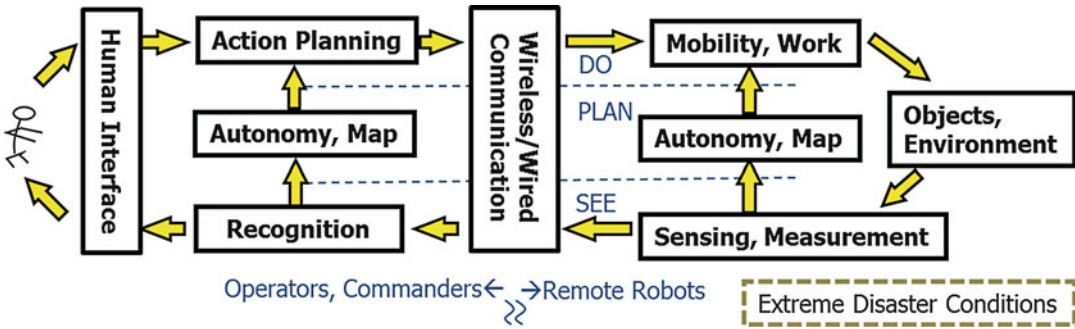
Summary and Future Directions

Data flow of disaster response robots is generally described by a feedback system as shown in Fig. 8. Robots change the states of objects and environment by movement and task execution. Sensors measure and recognize them, and their feedback enables the robots' autonomous motion and work. The sensed data are shown to operators via communication, data processing, and human interface. The operators give commands of motion and work to the system via the human interface. The system recognizes and transmits them to the robot.


Disaster Response Robot, Fig. 8 Data flow of remotely controlled disaster response robots

Each functional block has its own technical challenges to be fulfilled under extreme environments of disaster space in response to the objectives and the conditions. They should be solved technically in order to improve the robot performance. They include insufficient mobility in disaster spaces (steps, gaps, slippage, narrow space, obstacles, etc.), deficient workability (dexterity, accuracy, speed, force, work space, etc.), poor sensors and sensor data processing (image, recognition, etc.), lack of reliability and performance of autonomy (robot intelligence, multiagent collaboration, etc.), issues of wireless and wired communication (instability, delay, capacity, tether handling, etc.), operators' limitations (situation awareness, decision ability, fatigue, mistake, etc.), basic performances (explosion proof, weight, durability, portability, etc.), and system integration that combines the components into the solution. Mission critical planning and execution including human factors, training, role sharing, logistics, etc. have to be considered at the same time.

Research into systems and control is expected to solve the abovementioned challenges of components and systems. For example, intelligent control is essential for mobility and workability under extreme conditions; control of feedback systems including long delay and dynamic instability, control of human-in-loop systems, and system integration of heterogeneous systems are important research topics of systems and control.

In the research field of disaster robotics, various competitions of practical robots have been held, e.g., RoboCupRescue targeting CBRNE disasters, ELROB and euRathlon for field activities, MAGIC for multi-robot autonomy, and DARPA Robotics Challenge for humanoid robots in nuclear disasters. These competitions seek to stimulate solutions of the above-mentioned technical issues in different environments by providing practical test beds for advanced technology developments.

Discrete Event Systems and Hybrid Systems, Connections Between

Alessandro Giua
DIEE, University of Cagliari, Cagliari, Italy
LSIS, Aix-en-Provence, France

Abstract

The causes of the complex behavior typical of hybrid systems are multifarious and are commonly explained in the literature using paradigms that are mainly focused on the connections between time-driven and hybrid systems. In this entry, we recall some of these paradigms and further explore the connections between discrete event and hybrid systems from other perspectives. In particular, the role of abstraction in passing from a hybrid model to a discrete event one and vice versa is discussed.

Keywords

Hybrid system; Logical discrete event system; Timed discrete event system

Introduction

Hybrid systems combine the dynamics of both *time-driven systems* and *discrete event systems*.

The evolution of a *time-driven system* can be described by a differential equation (in continuous time) or by a difference equation (in discrete time). An example of such a system is the tank shown in Fig. 1 whose behavior, assuming the tank is not full, is ruled in continuous time t by the differential equation

$$\frac{d}{dt}V(t) = q_1(t) - q_2(t)$$

where V is the volume of liquid and q_1 and q_2 are, respectively, the input and output flow.

A *discrete event system* (Lafortune and Cassandras 2007; Seatzu et al. 2012) evolves in accordance with the abrupt occurrence, at possibly unknown irregular intervals, of physical events. Its states may have logical or symbolic, rather than numerical, values that change in response to events which may also be described in nonnumerical terms. An example of such a system is a robot that loads parts on a conveyor, whose behavior is described by the automaton in Fig. 2. The robot can be "idle," "loading" a part, or in an "error" state when a part is incorrectly positioned. The events that drive its evolution are a (grasp a part), b (part correctly loaded), c (part incorrectly positioned), and d (part repositioned). In a *logical* discrete event system (▶ Supervisory Control of Discrete-Event Systems), the timing of event occurrences are ignored, while in a *timed* discrete event system (▶ Models for Discrete Event Systems: An Overview), they are described by means of a suitable timing structure.

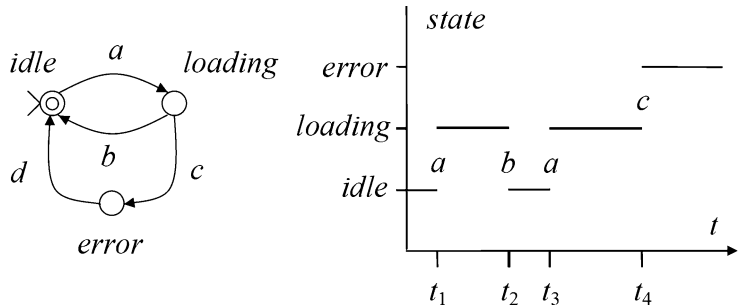
In a *hybrid system* (▶ Hybrid Dynamical Systems, Feedback Control of), time-driven and event-driven evolutions are simultaneously present and mutually dependent. As an example, consider a room where a thermostat maintains the temperature $x(t)$ between $x_a = 20\,^\circ\text{C}$ and $x_b = 22\,^\circ\text{C}$ by turning a heat pump on and off. Due to the exchange with the external environment at temperature $x_e \ll x(t)$, when the pump is off, the room temperature derivative is

$$\frac{d}{dt}x(t) = -k[x(t) - x_e]$$

where k is a suitable coefficient, while when the pump is on, the room temperature derivative is

$$\frac{d}{dt}x(t) = h(t) - k[x(t) - x_e]$$

where the positive term $h(t)$ is due to the heat pump. The hybrid automaton that describes this system is shown in Fig. 3.

The causes of the complex behavior typical of hybrid systems are multifarious, and among the paradigms commonly used in the literature to describe them, we mention three.
Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 1 A tank
Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 2 A machine with failures


Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 3 Hybrid automaton of the thermostat

- *Logically controlled systems.* Often, a physical system with a time-driven evolution is controlled in a feedback loop by means of a controller that implements discrete computations and event-based logic. This is the case of the thermostat mentioned above. Classes of systems that can be described by this paradigm are *embedded systems* or, when the feedback loop is closed through a communication network, *cyber-physical systems*.
- *State-dependent mode of operation.* A time-driven system can have different modes of evolution depending on its current state. As an example, consider a bouncing ball. While the ball is above the ground (vertical position $h > 0$) its behavior is that of a falling body subject to a constant gravitational force. However, when the ball collides with the ground

(vertical position $h = 0$), its behavior is that of a (partially) elastic body that bounces up. Classes of systems that can be described by this paradigm are *piecewise affine systems* and *linear complementarity system*.
- *Variable structure systems.* Some systems may change their structure assuming different configuration, each characterized by a different behavior. As an example, consider a multicell voltage converter composed by a cascade of elementary commutation cells: controlling some switches, it is possible to insert or remove cells so as to produce a desired output voltage signal. Classes of systems that can be described by this paradigm are *switched systems*.

While these are certainly appropriate and meaningful paradigms, they are mainly focused on the connections between time-driven and

hybrid systems. In the rest of this entry, we will discuss the connections between discrete event and hybrid systems from other different perspectives. The focus is strictly on modeling, thus approaches for analysis or control will not be discussed.
From Hybrid Systems to Discrete Event System by Modeling Abstraction

A *system* is a physical object, while a *model* is a (more or less accurate) mathematical description of its behavior that captures those features that are deemed mostly significant. In the previous pages, we have introduced different classes of systems, such as "time-driven systems," "discrete event systems," and "hybrid systems," but properly speaking, this taxonomy pertains to the models because the terms "time driven," "discrete event," or "hybrid" should be used to classify the mathematical description and not the physical object.

According to this view, a discrete event model is often perceived as a high-level description of a physical system where the time-driven dynamics are ignored or, at best, approximated by a timing structure. This procedure to derive a simpler model in a way that preserves the properties being analyzed while hiding the details that are of no interest is called *abstraction* (Alur et al. 2000).

Consider, as an example, the thermostat in Fig. 3. In such a system, the time-driven evolution determines a change in the temperature, which in turn – reaching a threshold – triggers the occurrence of an event that changes the discrete state. Assume one does not care about the exact form this triggering mechanism takes and is only interested in determining if the heat pump is turned on or off. In such a case, we can completely *abstract* the time-driven evolution obtaining a logical discrete event model such as the automaton in Fig. 4, where label *a* denotes the event *the temperature drops below* 20 °C and label *b* denotes the event *the temperature raises over* 22 °C.

For some purposes, e.g., to determine the utilization rate of the heat pump and thus its operating cost, the model in Fig. 4 is inadequate. In such a case, one can consider a less coarse

Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 4 Logical discrete event model of the thermostat

abstraction of the hybrid model in Fig. 3 obtaining a timed discrete event model such as the automaton in Fig. 4. Here, to each event is associated a firing delay: as an example, δ_a represents the time it takes – when the pump is off – to cool down until the lower temperature threshold is reached and event *a* occurs. The delay may be a deterministic value or even a random one to take into account the uncertainty due to non-modeled time-varying parameters such as the temperature of the external environment. Note that a new state (START) and a new event b' have now been introduced to capture the transient phase in which the room temperature, from the initial value $x(0) = 15$ °C, reaches the higher temperature threshold: in fact, event b' has a delay greater than the delay of event b.

Timed Discrete Event Systems Are Hybrid Systems

Properly speaking, all timed discrete event systems may also be seen as hybrid systems if one considers the dynamics of the timers – that specify the event occurrence – as elementary time-driven evolutions. In fact, the simplest model of hybrid systems is the *timed automaton* introduced by Alur and Dill (1994) whose main feature is the fact that each continuous variable $x(t)$ has a constant derivative $\dot{x}(t) = 1$ and thus can only describe the passage of time. Incidentally, we note that the term "timed automaton" is also used in the area of discrete event systems (Lafortune and Cassandras 2007) to denote an automaton in which a timing structure is associated to the events: such an example was shown in Fig. 5. To avoid any confusion, in the following, we denote the former model *Alur-Dill automaton* and the latter model *timed DES automaton*.

In Fig. 6 is shown an Alur-Dill automaton that describes the thermostat, where the time-driven dynamics have been abstracted and only the timing of event occurrence is modeled as in the timed DES automaton in Fig. 5. The only continuous variable is the value of a timer δ: when it goes beyond a certain threshold (e.g., $\delta > \delta_a$), an event occurs (e.g., event a) changing the discrete state (e.g., from OFF to ON) and resetting the timer to zero.

It is rather obvious that the behavior of the Alur-Dill automaton in Fig. 6 is equivalent to the behavior of timed DES automaton in Fig. 5. In the former model, the notion of time is encoded by means of an explicit continuous variable δ. In the latter model, the notion of time is implicitly encoded by the timer that during an evolution will be associated to each event. In both cases, however, the overall state of the systems is described by a pair $(\ell(t), x(t))$ where the first element ℓ takes value in a discrete set $\{START, ON, OFF\}$ and the second element is a vector (in this particular case with a single component) of timer valuations.

It should be pointed out that an Alur-Dill automaton may have a more complex structure than that shown in Fig. 6: as an example, the guard associated to a transition, i.e., the values of the timer that enable it, can be an arbitrary rectangular set. However, the same is also true for a timed discrete event system: several policies can be used to define the time intervals enabling an

event (enabling policy) or to specify when a timer is reset (memory policy) (Ajmone Marsan et al. 1995). Furthermore, timed discrete event system can have arbitrary stochastic timing structures (e.g., semi-Markovian processes, Markov chains, and queuing networks (Lafortune and Cassandras 2007)), not to mention the possibility of having an infinite discrete state space (e.g., timed Petri nets (Ajmone Marsan et al. 1995; David and Alla 2004)). As a result, we can say that timed DES automata are far more general than Alur-Dill automata and represent a meaningful subclass of hybrid systems.
From Discrete Event System to Hybrid Systems by Fluidization

The computational complexity involved in the analysis and optimization of real-scale problems often becomes intractable with discrete event models due to the very large number of reachable states, and a technique that has shown to be effective in reducing this complexity is called *fluidization* (▶ Applications of Discrete-Event Systems). It should be noted that the derivation of a fluid (i.e., hybrid) model from a discrete event one is yet an example of abstraction albeit going in opposite direction with respect to the examples discussed in the section "From Hybrid Systems to Discrete Event System by Modeling Abstraction" above.

The main drive that motivated the fluidization approach derives from the observation that some discrete event systems are "heavily populated" in the sense that there are many identical items in some component (e.g., clients in a queue). Fluidization consists in replacing the integer counter of the number of items by a real number and in approximating the "fast" discrete event
Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 5 Timed discrete event model of the thermostat

Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 6 Alur-Dill automaton of the thermostat

dynamics that describe how the counter changes by a continuous dynamics. This approach has been successfully used to study the performance optimization of fluid-queuing networks (Cassandras and Lygeros 2006) or Petri net models (Balduzzi et al. 2000; David and Alla 2004; Silva and Recalde 2004) with applications in domains such as manufacturing systems and communication networks. We also remark that in general, different fluid approximations are necessary to describe the same system, depending on its discrete state, e.g., in the manufacturing domain, machines working or down, buffers full or empty, and so on. Thus, the resulting model can be better described as a hybrid model, where different time-driven dynamics are associated to different discrete states.

There are many advantages in using fluid approximations. First, there is the possibility of considerable increase in computational efficiency because the simulation of a fluid model can often be performed much faster than that of its discrete event counterpart. Second, fluid approximations provide an aggregate formulation to deal with complex systems, thus reducing the dimension of the state space. Third, the resulting simple structures often allow explicit computation of performance measures. Finally, some design parameters in fluid models are continuous; hence, it is possible to use gradient information to speed up optimization and to perform sensitivity analysis (Balduzzi et al. 2000): in many cases, it has also been shown that fluid approximations do not introduce significant errors when carrying out performance analysis via simulation (▸ Perturbation Analysis of Discrete Event Systems).

DOC

Abstract

Discrete optimal control is a branch of mathematics which studies optimization procedures for controlled discrete-time models – that is, the optimization of a performance index associated with a discrete-time control system. This entry gives an introduction to the topic. The formulation of a general discrete optimal control problem is described, and applications to mechanical systems are discussed.

Keywords

Discrete mechanics; Discrete-time models; Symplectic integrators; Variational integrators

Definition

Discrete optimal control is a branch of mathematics which studies optimization procedures for controlled discrete-time models, that is, the optimization of a performance index associated to a discrete-time control system.

Motivation

Optimal control theory is a mathematical discipline with innumerable applications in both science and engineering. Discrete optimal control is concerned with control optimization for discrete-time models. Recently, in discrete optimal control theory, a great interest has appeared in developing numerical methods to optimally control real mechanical systems, as for instance, autonomous robotic vehicles in natural environments such as robotic arms, spacecrafts, or underwater vehicles.

During the last years, a huge effort has been made for the comprehension of the fundamental geometric structures appearing in dynamical systems, including control systems and optimal control systems. This new geometric understanding of those systems has made possible the construction of suitable numerical techniques for integration. A collection of ad hoc numerical methods are available for both dynamical and control systems. These methods have grown up accordingly with the needs in research coming from different fields such as physics and engineering. However, a new breed of ideas in numerical analysis has started recently. They incorporate the geometry of the systems into the analysis and that allows faster and more accurate algorithms and with less spurious effects than the traditional ones. All this gives birth to a new field called Geometric Integration (Hairer et al. 2002). For instance, numerical integrators for Hamiltonian systems should preserve the symplectic

structure underlying the geometry of the system. If so, they are called symplectic integrators.

Another approach used by more and more authors is based on the theory of discrete mechanics and variational integrators to obtain geometric integrators preserving some of the geometry of the original system (Hussein et al. 2006; Marsden and West 2001; Wendlandt and Marsden 1997a,b) (see also the section "Discrete Mechanics"). These geometric integrators are easily adapted and applied to a wide range of mechanical systems: forced or dissipative systems, holonomically constrained systems, explicitly time-dependent systems, reduced systems with frictional contact, nonholonomic dynamics, and multisymplectic field theories, among others.

As before, in optimal control theory, it is necessary to distinguish two kinds of numerical methods: the so-called direct and indirect methods. If we use direct methods, we first discretize the state and control variables, control equations, and cost functional, and then we solve a nonlinear optimization problem with constraints given by the discrete control equations, additional constraints, and boundary conditions (Bock and Plitt 1984; Bonnans and Laurent-Varin 2006; Hager 2001; Pytlak 1999). In this case, we typically need to solve a system of the type (see the section "Formulation of a General Discrete Optimal Control Problem")

$$\begin{cases} \text{minimize } F(X) \ X = (q^0, \ldots, q^N, u_1, \ldots u_N) \\ \quad \text{with } \Psi(X) = 0 \\ \quad\quad \Phi(X) \geq 0 \end{cases}$$

On the other hand, indirect methods consist of solving numerically the boundary value problem obtained from the equations after applying Pontryagin's Maximum Principle.

The combination of direct methods and discrete mechanics allows to obtain numerical control algorithms which are geometric structure preserving and exhibit a good long-time behavior (Bloch et al. 2013; Jiménez et al. 2013; Junge and Ober-Blöbaum 2005; Junge et al. 2006; Kobilarov 2008; Leyendecker et al. 2007; Ober-Blöbaum 2008; Ober-Blöbaum et al. 2011). Furthermore, it is possible to adapt many of

the techniques used for continuous control mechanical systems to the design of quantitative and qualitative accurate numerical methods for optimal control methods (reduction by symmetries, preservation of geometric structures, Lie group methods, etc.).

Formulation of a General Discrete Optimal Control Problem

Let M be an n-dimensional manifold, x denote the state variables in M for an agent's environment, and $u \in U \subset \mathbb{R}^m$ be the control or action that the agent chooses to accomplish a task or objective. Let $f_d(x, u) \in M$ be the resulting state after applying the control u to the state x. For instance, x may be the configuration of a vehicle at time t and u its fuel consumption, and then $f_d(x, u)$ is the new configuration of the vehicle at time $t + h$, with $t, h > 0$. Of course, we want to minimize the fuel consumption. Hence, the optimal control problem consists of finding the cheapest way to move the system from a given initial position to a final state. The problem can be mathematically described as follows: find a sequence of controls $(u_0, u_1, \ldots, u_{N-1})$ and a sequence of states $(x_0, x_1, \ldots, x_N)$ such that

$$x_{k+1} = f_d(k, x_k, u_k), \qquad (1)$$

where $x_k \in M$, $u_k \in U$, and the total cost

$$\mathcal{C}_d = \sum_{k=0}^{N-1} C_d(k, x_k, u_k) + \phi_d(N, x_N) \qquad (2)$$

is minimized where ϕ_d is a function of the final time and state at the final time (the terminal payoff) and C_d is a function depending on the discrete time, the state, and the control at each intermediate discrete time k (the running payoff).

To solve the discrete optimal control problem determined by Eqs. (1) and (2), it is possible to use the classical Lagrangian multiplier approach. In this case, we consider the control equations (1) as constraint equations associating a Lagrange multiplier to each constraint. Assume for simplicity that $M = \mathbb{R}^n$. Then, we construct the augmented cost function

$$\tilde{\mathcal{C}}_d = \sum_{k=0}^{N-1} \Big[p_{k+1} \left(x_{k+1} - f_d(k, x_k, u_k) \right)$$
$$- C_d(k, x_k, u_k) \Big] - \Phi_d(N, x_N) \qquad (3)$$

where $p_k \in \mathbb{R}^n$, $k = 1, \ldots, N$, are considered as the Lagrange multipliers. The notation xy is used for the scalar (inner) product $x \cdot y$ of two vectors in $\mathbb{R}^n$.

From the *pseudo-Hamiltonian function*

$$H_d(k, x_k, p_{k+1}, u_k) = p_{k+1} f_d(k, x_k, u_k)$$
$$- C_d(k, x_k, u_k),$$

we deduce the necessary conditions for a constrained minimum:

$$x_{k+1} = \frac{\partial H_d}{\partial p}(k, x_k, p_{k+1}, u_k)$$
$$= f_d(k, x_k, u_k) \qquad (4)$$
$$p_k = \frac{\partial H_d}{\partial q}(k, x_k, p_{k+1}, u_k)$$
$$= p_{k+1} \frac{\partial f_d}{\partial q}(k, x_k, u_k)$$
$$- \frac{\partial C_d}{\partial q}(k, x_k, u_k) \qquad (5)$$
$$0 = \frac{\partial H_d}{\partial u}(k, x_k, p_{k+1}, u_k)$$
$$= p_{k+1} \frac{\partial f_d}{\partial u}(k, x_k, u_k)$$
$$- \frac{\partial C_d}{\partial u}(k, x_k, u_k) \qquad (6)$$

where $0 \le k \le N - 1$. Moreover, we have some boundary conditions

$$x_0 \text{ is given and } p_N = -\frac{\partial \Phi_d}{\partial q}(N, x_N) \quad (7)$$

The variable p_k is called the costate of the system and Eq. (5) is called the adjoint equation. Observe that the recursion of x_k given by Eq. (4) develops forward in the discrete time, but the recursion of the costate variable is backward in the discrete time.

In the sequel, it is assumed the following regularity condition:

$$\det\left(\frac{\partial^2 H_d}{\partial u^a \partial u^b}\right) \neq 0$$

where $1 \leq a, b \leq m$, and $(u^a) \in U \subseteq \mathbb{R}^m$. Applying the implicit function theorem, we obtain from Eq. (1) that locally $u_k = g(k, x_k, p_{k+1})$. Defining the function

$$\tilde{H}_d : \quad \mathbb{Z} \times \mathbb{R}^{2n} \longrightarrow \mathbb{R}$$
$$(k, q_k, p_{k+1}) \longmapsto H_d(k, q_k, p_{k+1}, u_k)$$

Equations (4) and (5) are rewritten as the following discrete Hamiltonian system:

$$x_{k+1} = \frac{\partial \tilde{H}_d}{\partial p}(k, x_k, p_{k+1}) \qquad (8)$$

$$p_k = \frac{\partial \tilde{H}_d}{\partial q}(k, x_k, p_{k+1}) \qquad (9)$$

The expression of the solutions of the optimal control problem as a discrete Hamiltonian system (under some regularity properties) is important since it indicates that the discrete evolution is preserving symplecticity. A simple proof of this fact is the following (de León et al. (2007)). Construct the following function

$$G_k(x_k, x_{k+1}, p_{k+1}) = \tilde{H}_d(k, x_k, p_{k+1})$$
$$- p_{k+1} x_{k+1},$$

with $0 \leq k \leq N - 1$. For each fixed k:

$$dG_k = \frac{\partial \tilde{H}_d}{\partial q}(k, x_k, p_{k+1})\, dx_k$$
$$+ \frac{\partial \tilde{H}_d}{\partial p}(k, x_k, p_{k+1})\, dp_{k+1}$$
$$- p_{k+1} dx_{k+1} - x_{k+1} dp_{k+1}\,.$$

Thus, along solutions of Eqs. (8) and (9), we have that $dG_{k|\text{solutions}} = p_k dx_k - p_{k+1} dx_{k+1}$ which implies $dx_k \wedge dp_k = dx_{k+1} \wedge dp_{k+1}$.

In the next section, we will study the case of discrete optimal control of mechanical systems.

First, we will need an introduction to discrete mechanics and variational integrators.

Discrete Mechanics

Let Q be an n-dimensional differentiable manifold with local coordinates (q^i), $1 \leq i \leq n$. We denote by TQ its tangent bundle with induced coordinates $(q^i, \dot{q}^i)$. Let $L: TQ \to \mathbb{R}$ be a Lagrangian function; the associated Euler–Lagrange equations are given by

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}^i}\right) - \frac{\partial L}{\partial q^i} = 0, \quad 1 \leq i \leq n. \quad (10)$$

These equations are a system of implicit second-order differential equations. Assume that the Lagrangian is **regular**, that is, the matrix $\left(\frac{\partial^2 L}{\partial \dot{q}^i \partial \dot{q}^j}\right)$ is non-singular. It is well known that the origin of these equations is variational (see Marsden and West 2001). Variational integrators retain this variational character and also some of the key geometric properties of the continuous system, such as symplecticity and momentum conservation (see Hairer et al. 2002 and references therein). In the following, we summarize the main features of this type of numerical integrators (Marsden and West 2001). A **discrete Lagrangian** is a map $L_d: Q \times Q \to \mathbb{R}$, which may be considered as an approximation of the integral action defined by a continuous Lagrangian $L: TQ \to \mathbb{R}: L_d(q_0, q_1) \approx \int_0^h L(q(t), \dot{q}(t))\, dt$ where $q(t)$ is a solution of the Euler–Lagrange equations for L with $q(0) = q_0$, $q(h) = q_1$, and $h > 0$ being enough small.

Remark 1 The Cartesian product $Q \times Q$ is equipped with an interesting differential structure, called Lie groupoid, which allows the extension of variational calculus to more general settings (see Marrero et al. 2006, 2010 for more details).

Define the **action sum** $S_d: Q^{N+1} \to \mathbb{R}$, corresponding to the Lagrangian L_d by $S_d = \sum_{k=1}^{N} L_d(q_{k-1}, q_k)$, where $q_k \in Q$ for $0 \leq k \leq N$ and N is the number of steps. The discrete variational principle states that the solutions of

the discrete system determined by L_d must extremize the action sum given fixed endpoints q_0 and q_N. By extremizing S_d over q_k, $1 \leq k \leq N-1$, we obtain the system of difference equations

$$D_1 L_d(q_k, q_{k+1}) + D_2 L_d(q_{k-1}, q_k) = 0, \quad (11)$$

or, in coordinates,

$$\frac{\partial L_d}{\partial x^i}(q_k, q_{k+1}) + \frac{\partial L_d}{\partial y^i}(q_{k-1}, q_k) = 0,$$

where $1 \leq i \leq n$, $1 \leq k \leq N-1$, and x, y denote the n-first and n-second variables of the function L_d, respectively.

These equations are usually called the **discrete Euler–Lagrange equations**. Under some regularity hypotheses (the matrix $D_{12}L_d(q_k, q_{k+1})$ is regular), it is possible to define a (local) discrete flow $\Upsilon_{L_d} \colon Q \times Q \to Q \times Q$, by $\Upsilon_{L_d}(q_{k-1}, q_k) = (q_k, q_{k+1})$ from (11). Define the discrete Legendre transformations associated to L_d as

$$\mathbb{F}^- L_d \colon Q \times Q \;\to\; T^*Q$$
$$(q_0, q_1) \longmapsto (q_0, -D_1 L_d(q_0, q_1)),$$
$$\mathbb{F}^+ L_d \colon Q \times Q \;\to\; T^*Q$$
$$(q_0, q_1) \longmapsto (q_1, D_2 L_d(q_0, q_1)),$$

and the discrete Poincaré–Cartan 2-form $\omega_d = (\mathbb{F}^+ L_d)^* \omega_Q = (\mathbb{F}^- L_d)^* \omega_Q$, where ω_Q is the canonical symplectic form on T^*Q. The discrete algorithm determined by Υ_{L_d} preserves the symplectic form ω_d, i.e., $\Upsilon_{L_d}^* \omega_d = \omega_d$. Moreover, if the discrete Lagrangian is invariant under the diagonal action of a Lie group G, then the discrete momentum map $J_d \colon Q \times Q \to \mathfrak{g}^*$ defined by

$$\langle J_d(q_k, q_{k+1}), \xi \rangle = \langle D_2 L_d(q_k, q_{k+1}),$$
$$\xi_Q(q_{k+1}) \rangle$$

is preserved by the discrete flow. Therefore, these integrators are symplectic-momentum preserving. Here, ξ_Q denotes the fundamental vector field determined by $\xi \in \mathfrak{g}$, where $\mathfrak{g}$ is the Lie algebra of G. As stated in Marsden and West (2001), discrete mechanics is inspired by discrete

formulations of optimal control problems (see Cadzow 1970; Hwang and Fan 1967; Jordan and Polak 1964).

Discrete Optimal Control of Mechanical Systems

Consider a mechanical system whose configuration space is an n-dimensional differentiable manifold Q and whose dynamics is determined by a Lagrangian $L \colon TQ \to \mathbb{R}$. The control forces are modeled as a mapping $f \colon TQ \times U \to T^*Q$, where $f(v_q, u) \in T_q^* Q$, $v_q \in T_q Q$ and $u \in U$, being U the control space. Observe that this last definition also covers configuration and velocity-dependent forces such as dissipation or friction (see Ober-Blöbaum et al. 2011).

The motion of the mechanical system is described by applying the principle of **Lagrange–D'Alembert**, which requires that the solutions $q(t) \in Q$ must satisfy

$$\delta \int_0^T L(q(t), \dot{q}(t)) \, dt$$
$$+ \int_0^T f(q(t), \dot{q}(t), u(t)) \, \delta q(t) \, dt = 0,$$
$$(12)$$

where $(q, \dot{q})$ are the local coordinates of TQ and where we consider arbitrary variations $\delta q(t) \in T_{q(t)}Q$ with $\delta q(0) = 0$ and $\delta q(T) = 0$ (since we are prescribing fixed initial and final conditions $(q(0), \dot{q}(0))$ and $(q(T), \dot{q}(T))$).

As we consider an optimal control problem, the forces f must be chosen, if they exist, as the ones that extremize the **cost functional**:

$$\int_0^T C(q(t), \dot{q}(t), u(t)) \, dt$$
$$+ \Phi(q(T), \dot{q}(T), u(T)), \quad (13)$$

where $C \colon TQ \times U \to \mathbb{R}$.

The optimal equations of motion can now be derived using Pontryagin's Maximum Principle. In general, it is not possible to explicitly integrate these equations. Then, it is necessary to apply a numerical method. In this work, using

discrete variational techniques, we first discretize the Lagrange–d'Alembert principle and then the cost functional. We obtain a numerical method that preserves some geometric features of the original continuous system as described in the sequel.

Discretization of the Lagrangian and Control Forces

To discretize this problem, we replace the tangent space TQ by the Cartesian product $Q \times Q$ and the continuous curves by sequences $q_0, q_1, \ldots q_N$ (we are using N steps, with time step h fixed, in such a way $t_k = kh$ and $Nh = T$). The discrete Lagrangian $L_d : Q \times Q \to \mathbb{R}$ is constructed as an approximation of the action integral in a single time step (see Marsden and West 2001), that is,

$$L_d(q_k, q_{k+1}) \approx \int_{kh}^{(k+1)h} L(q(t), \dot{q}(t)) \, dt.$$

We choose the following discretization for the external forces: $f_d^{\pm} : Q \times Q \times U \to T^*Q$, where $U \subset \mathbb{R}^m, \ m \leq n$, such that

$$f_d^-(q_k, q_{k+1}, u_k) \in T_{q_k}^* Q,$$
$$f_d^+(q_k, q_{k+1}, u_k) \in T_{q_{k+1}}^* Q.$$

f_d^+ and f_d^- are right and left discrete forces (see Ober-Blöbaum et al. 2011).

Discrete Lagrange–d'Alembert Principle

Given such forces, we define the discrete Lagrange–d'Alembert principle, which seeks sequences $\{q_k\}_{k=0}^N$ that satisfy

$$\delta \sum_{k=0}^{N-1} L_d(q_k, q_{k+1})$$
$$+ \sum_{k=0}^{N-1} \Big(f_d^-(q_k, q_{k+1}, u_k) \, \delta q_k$$
$$+ f_d^+(q_k, q_{k+1}, u_k) \, \delta q_{k+1} \Big) = 0,$$

for arbitrary variations $\{\delta q_k\}_{k=0}^N$ with $\delta q_0 = \delta q_N = 0$. After some straightforward

manipulations, we arrive to the forced discrete Euler–Lagrange equations

$$D_2 L_d(q_{k-1}, q_k) + D_1 L_d(q_k, q_{k+1})$$
$$+ f_d^+(q_{k-1}, q_k, u_{k-1})$$
$$+ f_d^-(q_k, q_{k+1}, u_k) = 0,$$
$$(14)$$

with $k = 1, \ldots, N - 1$.

Boundary Conditions

For simplicity, we assume that the boundary conditions of the continuous optimal control problem are given by $q(0) = x_0, \dot{q}(0) = v_0, q(T) = x_T, \dot{q}(T) = v_T$. To incorporate these conditions to the discrete setting, we use both the continuous and discrete Legendre transformations. From Marsden and West (2001), given a forced system, we can define the discrete momenta

$$\mu_k = -D_1 L_d(q_k, q_{k+1}) - f_d^-(q_k, q_{k+1}, u_k),$$
$$\mu_{k+1} = D_2 L_d(q_k, q_{k+1}) + f_d^+(q_k, q_{k+1}, u_k).$$

From the continuous Lagrangian, we have the momenta

$$p_0 = \mathbb{F}L(x_0, v_0) = (x_0, \frac{\partial L}{\partial v}(x_0, v_0))$$
$$p_T = \mathbb{F}L(x_T, v_T) = \left(x_T, \frac{\partial L}{\partial v}(x_T, v_T) \right)$$

Therefore, the natural choice of boundary conditions is

$$x_0 = q_0, \qquad x_T = q_N$$
$$\mathbb{F}L(x_0, v_0) = -D_1 L_d(q_0, q_1) - f_d^-(q_0, q_1, u_0)$$
$$\mathbb{F}L(x_T, v_T) = D_2 L_d(q_{N-1}, q_N)$$
$$+ f_d^+(q_{N-1}, q_N, u_{N-1})$$

that we add to the discrete optimal control problem.

Discrete Cost Function

We can also approximate the cost functional (13) in a single time step h by

$$
\begin{aligned}
&C_d(q_k, q_{k+1}, u_k) \\
&\approx \int_{kh}^{(k+1)h} C(q(t), \dot{q}(t), u(t))\, dt,
\end{aligned}
$$

yielding the **discrete cost functional**:

$$
\sum_{k=0}^{N-1} C_d(q_k, q_{k+1}, u_k) + \Phi_d(q_{N-1}, q_N, u_{N-1}).
$$

Discrete Optimal Control Problem

With all these elements, we have the following discrete optimal control problem:

$$
\begin{aligned}
\min \sum_{k=0}^{N-1} &C_d(q_k, q_{k+1}, u_k) \\
&+ \Phi_d(q_{N-1}, q_N, u_{N-1})
\end{aligned}
$$

subject to

$$
\begin{aligned}
&D_2 L_d(q_{k-1}, q_k) + D_1 L_d(q_k, q_{k+1}) \\
&+ f_d^+(q_{k-1}, q_k, u_{k-1}) + f_d^-(q_k, q_{k+1}, u_k) = 0, \\
&x_0 = q_0, \qquad x_T = q_N \\
&\frac{\partial L}{\partial v}(x_0, v_0) = -D_1 L_d(q_0, q_1) - f_d^-(q_0, q_1, u_0) \\
&\frac{\partial L}{\partial v}(x_T, v_T) = D_2 L_d(q_{N-1}, q_N) \\
&\qquad\qquad\quad + f_d^+(q_{N-1}, q_N, u_{N-1})
\end{aligned}
$$

with $k = 1, \ldots, N-1$ (see Jiménez and Martín de Diego 2010; Jiménez et al. 2013 for a modification of these equations admitting piecewise controls).

The system now is a constrained nonlinear optimization problem, that is, it corresponds to the minimization of a function subject to algebraic constraints. The necessary conditions for optimality are derived applying nonlinear programming optimization. For the concrete implementation, it is possible to use sequential quadratic programming (SQP) methods to numerically solve the nonlinear optimization problem (Ober-Blöbaum et al. 2011).

Optimal Control Systems with Symmetries

In many interesting cases, the continuous optimal control of a mechanical system is defined on a Lie group and the Lagrangian, cost function, control forces are invariant under the group action. The goal is again the same as in the previous section, that is, to move the system from its current state to a desired state in an optimal way. In this particular case, it is possible to adapt the contents of the section "Discrete Mechanics" in a similar way to the continuous case (from the standard Euler–Lagrange equations to the Euler–Poincaré equations) and to produce the so-called Lie group variational integrators. These methods preserve the Lie group structure avoiding the use of local charts, projections, or constraints. Based on these methods, for the case of controlled mechanical systems, we produce the discrete Euler–Poincaré equations with controls and the discrete cost function. Consequently, it is possible to deduce necessary optimality conditions for this class of invariant systems (see Bloch et al. 2009; Bou-Rabee and Marsden 2009; Hussein et al. 2006; Kobilarov and Marsden 2011).

Distributed Model Predictive Control

Gabriele Pannocchia
University of Pisa, Pisa, Italy

Abstract

Distributed model predictive control refers to a class of predictive control architectures in which a number of local controllers manipulate a subset of inputs to control a subset of outputs (states) composing the overall system. Different levels of communication and (non)cooperation exist, although in general the most compelling properties can be established only for cooperative schemes,

those in which all local controllers optimize local inputs to minimize the same plantwide objective function. Starting from state-feedback algorithms for constrained linear systems, extensions are discussed to cover output feedback, reference target tracking, and nonlinear systems. An outlook of future directions is finally presented.

Keywords

Constrained large-scale systems; Cooperative control systems; Interacting dynamical systems

Introduction and Motivations

Large-scale systems (e.g., industrial processing plants, power generation networks, etc.) usually comprise several interconnected units which may exchange material, energy, and information streams. The overall effectiveness and profitability of such large-scale systems depend strongly on the level of local effectiveness and profitability of each unit but also on the level of interactions among the different units. An overall optimization goal can be achieved by adopting a single *centralized* model predictive control (MPC) system (Rawlings and Mayne 2009) in which *all* control input trajectories are optimized simultaneously to minimize a *common* objective.

This choice is often avoided for several reasons. When the overall number of inputs and states is very large, a single optimization problem may require computational resources (CPU time, memory, etc.) that are not available and/or compatible with the system's dynamics. Even if these limitations do no hold, it is often the case that organizational reasons require the use of smaller, local controllers, which are easier to coordinate and maintain.

Thus, industrial control systems are often *decentralized*, i.e., the overall system is divided into (possibly mildly coupled) subsystems and a local controller is designed for each unit disregarding the interactions from/to other subsystems. Depending on the extent of dynamic coupling, it is well known that the performance of such decentralized systems may be poor, and stability

properties may be even lost. *Distributed* predictive control architectures arise to meet performance specifications (stability at minimum) similar to centralized predictive control systems, still retaining the modularity and local character of the optimization problems solved by each controller.

Definitions and Architectures for Constrained Linear Systems

Subsystem Dynamics, Constraints, and Objectives

We start the description of distributed MPC algorithms by considering an overall discrete-time linear time-invariant system in the form:

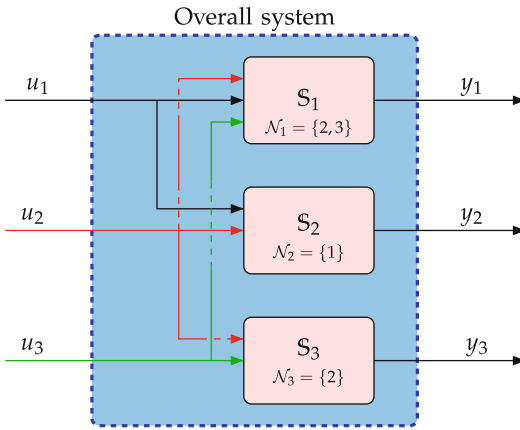
$$x^+ = Ax + Bu, \quad y = Cx \qquad (1)$$

in which $x \in \mathbb{R}^n$ and $x^+ \in \mathbb{R}^n$ are, respectively, the system state at a given time and at a successor time: $u \in \mathbb{R}^m$ is the input: and $y \in \mathbb{R}^p$ is the output.

We consider that the overall system (1) is divided into M subsystems, $\mathbb{S}_i$, defined by (disjoint) sets of inputs and outputs (states), and each $\mathbb{S}_i$ is regulated by a *local* MPC. For each $\mathbb{S}_i$, we denote by $y_i \in \mathbb{R}^{p_i}$ its output, by $x_i \in \mathbb{R}^{n_i}$ its state, and by $u_i \in \mathbb{R}^{m_i}$ the control input computed by the ith MPC. Due to interactions among subsystems, the local output y_i (and state x_i) is affected by control inputs computed by (some) other MPCs. Hence, the dynamics of $\mathbb{S}_i$ can be written as

$$x_i^+ = A_i x_i + B_i u_i + \sum_{j \in \mathcal{N}_i} B_{ij} u_j, \quad y_i = C_i x_i \tag{2}$$

in which $\mathcal{N}_i$ denotes the indices of *neighbors* of $\mathbb{S}_i$, i.e., the subsystems whose inputs have an influence on the states of $\mathbb{S}_i$. To clarify the notation, we depict in Fig. 1 the case of three subsystems, with neighbors $\mathcal{N}_1 = \{2, 3\}$, $\mathcal{N}_2 = \{1\}$, and $\mathcal{N}_3 = \{2\}$.

Without loss of generality, we assume that each pair (A_i, B_i) is stabilizable. Moreover, the state of each subsystem x_i is assumed known (to the ith MPC) at each decision time. For each subsystem $\mathbb{S}_i$, inputs are required to fulfill (hard) constraints:


Distributed Model Predictive Control, Fig. 1
Interconnected systems and neighbors definition

$$u_i \in \mathbb{U}_i, \qquad i = 1, \ldots, M \qquad (3)$$

in which $\mathbb{U}_i$ are polyhedrons containing the origin in their interior. Moreover, we consider a quadratic stage cost function $\ell_i(x, u) \triangleq \frac{1}{2}(x'Q_i x + u'R_i u)$ and a terminal cost function $V_{fi}(x) \triangleq \frac{1}{2}x'P_i x$, with $Q_i \in \mathbb{R}^{n_i \times n_i}$, $R_i \in \mathbb{R}^{m_i \times m_i}$, and $P_i \in \mathbb{R}^{n_i \times n_i}$ positive definite. Without loss of generality, let $x_i(0)$ be the state of $\mathbb{S}_i$ at the current decision time. Consequently, the finite-horizon cost function associated with $\mathbb{S}_i$ is given by:

$$V_i(x_i(0), \mathbf{u}_i, \{\mathbf{u}_j\}_{j \in \mathcal{N}_i}) \triangleq \sum_{i=0}^{N-1} \ell_i(x_i(k), u_i(k))$$
$$+ V_{fi}(x_i(N)) \qquad (4)$$

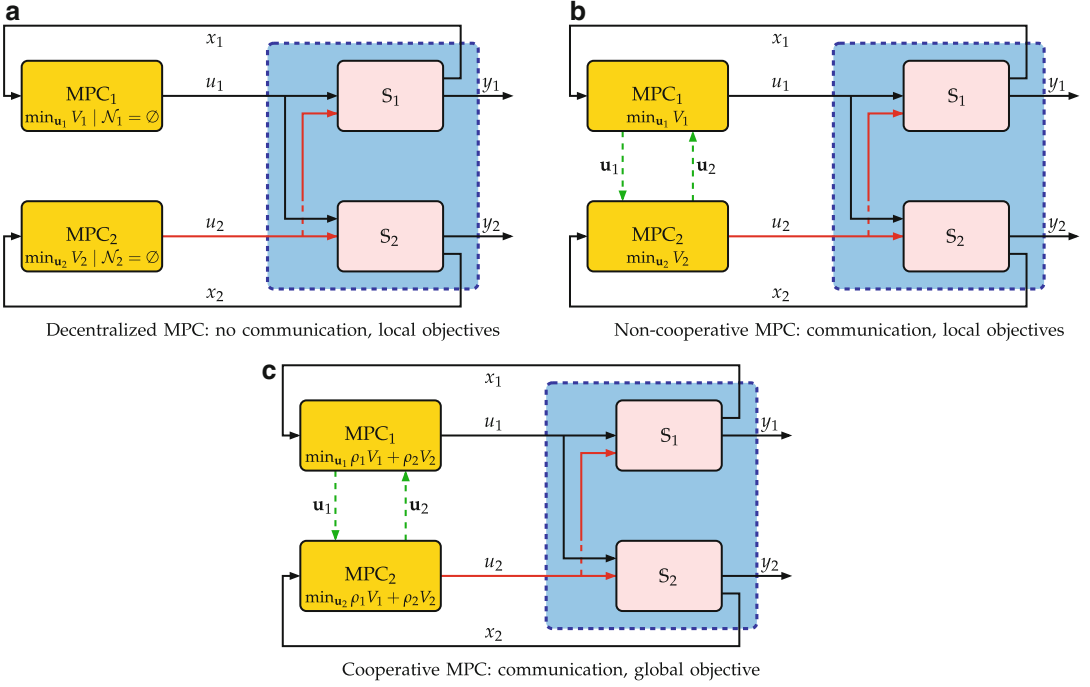
in which $\mathbf{u}_i = (u_i(0), u_i(1), \ldots, u_i(N-1))$ is a finite-horizon sequence of control inputs of $\mathbb{S}_i$, and $\mathbf{u}_j$ is similarly defined as a sequence of control inputs of each neighbor $j \in \mathcal{N}_i$. Notice that $V_i(\cdot)$ is a function of neighbors' input sequences, $\{\mathbf{u}_j\}_{j \in \mathcal{N}_i}$, due to the dynamics (2).

Decentralized, Noncooperative, and Cooperative Predictive Control Architectures

Several levels of communications and (non) cooperation can exist among the controllers, as depicted in Fig. 2 for the case of two subsystems.

In *decentralized* MPC architectures, interactions among subsystems are neglected by forcing $\mathcal{N}_i = \varnothing$ for all i even if this is not true. That is, the subsystem model used in each local controller, instead of (2), is simply

$$x_i^+ = A_i x_i + B_i u_i, \, y_i = C_i x_i \qquad (5)$$

Therefore, an inherent mismatch exists between the model used by the local controllers (5) and the actual subsystem dynamics (2). Each local MPC solves the following finite-horizon optimal control problem (FHOCP):


$$\mathbb{P}_i^{\text{De}} : \min_{\mathbf{u}_i} V_i(\cdot) \quad \text{s.t. } \mathbf{u}_i \in \mathbb{U}_i^N, \mathcal{N}_i = \varnothing \qquad (6)$$

We observe that in this case, $V_i(\cdot)$ *depends only* on local inputs, $\mathbf{u}_i$, because it is assumed that $\mathcal{N}_i = \varnothing$. Hence, each $\mathbb{P}_i^{\text{De}}$ is solved independently of the neighbors computations, and no iterations are performed. Clearly, depending on the actual level of interactions among subsystems, decentralized MPC architectures can perform poorly, namely, being non-stabilizing. Performance certifications are still possible resorting to robust stability theory, i.e., by treating the neglected dynamics $\sum_{j \in \mathcal{N}_i} B_{ij} u_j$ as (bounded) disturbances (Riverso et al. 2013).

In *noncooperative* MPC architectures, the existing interactions among the subsystems are fully taken into account through (2). Given a known value of the neighbors' control input sequences, $\{\mathbf{u}_j\}_{j \in \mathcal{N}_i}$, each local MPC solves the following FHOCP:

$$\mathbb{P}_i^{\text{NCDi}} : \quad \min_{\mathbf{u}_i} V_i(\cdot) \text{ s.t. } \mathbf{u}_i \in \mathbb{U}_i^N \qquad (7)$$

The obtained solution can be exchanged with the other local controllers to update the assumed neighbors' control input sequences, and iterations can be performed. We observe that this approach is noncooperative because local controllers try to optimize different, possibly competing, objectives. In general, no convergence is guaranteed in noncooperative iterations, and when this scheme converges, it leads to a so-called Nash equilibrium. However, the achieved local control inputs do not have proven stability properties (Rawlings

Distributed Model Predictive Control, Fig. 2 Three distributed control architectures: decentralized MPC, noncooperative MPC, and cooperative MPC

and Mayne 2009, §6.2.3). To ensure closed-loop stability, variants can be formulated by including a sequential solution of local MPC problems, exploiting the notion (if any) of an auxiliary stabilizing decentralized control law non-iterative noncooperative schemes are also proposed, in which stability guarantees are provided by ensuring a decrease of a centralized Lyapunov function at each decision time.

Finally, in *cooperative* MPC architectures, each local controller optimizes a common (plantwide) objective:

$$V(x(0), \mathbf{u}) \stackrel{\Delta}{=} \sum_{i=1}^{M} \rho_i V_i(x_i(0), \mathbf{u}_i, \{\mathbf{u}_j\}_{j \in \mathcal{N}_i}) \tag{8}$$

in which $\rho_i > 0$, for all i, are given scalar weights and $\mathbf{u} \stackrel{\Delta}{=} (\mathbf{u}_1, \ldots, \mathbf{u}_M)$ is the overall control sequence. In particular, given a known value of other subsystems' control input sequences, $\{\mathbf{u}_j\}_{j \neq i}$, each local MPC solves the following FHOCP:

$$\mathbb{P}_i^{\text{CDi}} : \quad \min_{\mathbf{u}_i} V(\cdot) \quad \text{s.t.} \ \mathbf{u}_i \in \mathbb{U}_i^N \tag{9}$$

As in noncooperative schemes, the obtained solution can be exchanged with the other local controllers, and further iterations can be performed. Notice that in $\mathbb{P}_i^{\text{CDi}}$, the (possible) implications of the local control sequence $\mathbf{u}_i$ to all other subsystems' objectives, $V_j(\cdot)$ with $j \neq i$ are taken into account, as well as the effect of the neighbors' sequences $\{\mathbf{u}_j\}_{j \in \mathcal{N}_i}$ on the local state evolution through (2). Clearly, this approach is termed cooperative because all controllers compute *local* inputs to minimize a *global* objective. Convergence of cooperative iterations is guaranteed, and under suitable assumptions the converged solution is the centralized Pareto-optimal solution (Rawlings and Mayne 2009, §6.2.4). Furthermore, the achieved local control inputs have proven stabilizing properties (Stewart et al. 2010). Variants are also proposed in which each controller still optimizes a local objective, but cooperative iterations are performed to ensure a

decrease of the global objective at each decision time (Maestre et al. 2011).

Cooperative Distributed MPC

Cooperative schemes are preferable over noncooperative schemes from many points of view, namely, in terms of superior theoretical guarantees and no larger computational requirements. In this section we focus on a prototype cooperative distributed MPC algorithm adapted from Stewart et al. (2010), highlighting the required computations and discussing the associated theoretical properties and guarantees.

Basic Algorithm
We present in Algorithm 1 a streamlined description of a cooperative distributed MPC algorithm, in which each local controller solves $\mathbb{P}_i^{\text{CDi}}$, given a previously computed value of all other subsystems' input sequences. For each local controller, the new iterate is defined as a convex combination of the newly computed solution with the previous iteration. A relative tolerance is defined, so that cooperative iterations stop when all local controllers have computed a new iterate sufficiently close to the previous one. A maximum number of cooperative iterations can also be defined, so that a finite bound on the execution time can be established.

Algorithm 1 *(Cooperative MPC).* **Require:** Overall warm start $\mathbf{u}^0 \triangleq (\mathbf{u}_1^0, \ldots, \mathbf{u}_M^0)$, convex step weights $w_i > 0$, s.t. $\sum_{i=1}^M w_i = 1$, relative tolerance parameter $\varepsilon > 0$, maximum cooperative iterations $c_{\max}$

1: Initialize: $c \leftarrow 0$ and $e_i \leftarrow 2\epsilon$ for $i = 1, \ldots, M$.
2: **while** $(c < c_{\max})$ **and** $(\exists i \,|\, e_i > \epsilon)$ **do**
3:   $c \leftarrow c + 1$.
4:   **for** $i = 1$ **to** M **do**
5:     Solve $\mathbb{P}_i^{\text{CDi}}$ in (9) obtaining $\mathbf{u}_i^*$.
6:   **end for**
7:   **for** $i = 1$ **to** M **do**
8:     Define new iterate: $\mathbf{u}_i^c \triangleq w_i \mathbf{u}_i^* + (1 - w_i) \mathbf{u}_i^{c-1}$.
9:     Compute convergence error: $e_i \triangleq \frac{\|\mathbf{u}_i^c - \mathbf{u}_i^{c-1}\|}{\|\mathbf{u}_i^{c-1}\|}$.
10:   **end for**
11: **end while**
12: **return** Overall solution: $\mathbf{u}^c \triangleq (\mathbf{u}_1^c, \ldots, \mathbf{u}_M^c)$.

We observe that Step 8 implicitly defines the new overall iterate as a convex combination of the overall solutions *achieved* by each controller, that is,

$$\mathbf{u}^c = \sum_{i=1}^M w_i (\mathbf{u}_1^{c-1}, \ldots, \mathbf{u}_i^*, \ldots, \mathbf{u}_M^{c-1}) \quad (10)$$

It is also important to observe that Steps 5, 8, and 9 are performed separately by each controller.

Properties
The basic cooperative MPC described in Algorithm 1 enjoys several nice theoretical and practical properties, as detailed (Rawlings and Mayne 2009, §6.3.1):
1. *Feasibility of each iterate*: $\mathbf{u}_i^{c-1} \in \mathbb{U}_i^N$ implies $\mathbf{u}_i^c \in \mathbb{U}_i^N$, for all $i = 1, \ldots, M$ and $c \in \mathbb{I}_{>0}$.
2. *Cost decrease at each iteration*: $V(x(0), \mathbf{u}^c) \leq V(x(0), \mathbf{u}^{c-1})$ for all $c \in \mathbb{I}_{>0}$.
3. *Cost convergence to the centralized optimum*: $\lim_{c \to \infty} V(x(0), \mathbf{u}^c) = \min_{\mathbf{u} \in \mathbb{U}^N} V(x(0), u)$, in which $\mathbb{U} \triangleq \mathbb{U}_1 \times \cdots \times \mathbb{U}_M$.

Resorting to suboptimal MPC theory, the above properties (1) and (2) can be exploited to show that the origin of closed-loop system

$$x^+ = Ax + B\kappa^c(x), \text{ with } \kappa^c(x) \triangleq u^c(0) \quad (11)$$

is *exponentially stable* for *any finite* $c \in \mathbb{I}_{>0}$. This result is of paramount (practical and theoretical) importance because it ensures closed-loop stability using cooperative distributed MPC with any finite number of cooperative iterations. As in centralized MPC based on the solution of a FHOCP (Rawlings and Mayne 2009, §2.4.3), particular care of the terminal cost function $V_{fi}(\cdot)$ is necessary, possibly in conjunction with a terminal constraint $x_i(N) \in \mathbb{X}_{fi}$. Several options can be adopted as discussed, e.g., in Stewart et al. (2010, 2011).

Moreover, the results in Pannocchia et al. (2011) can be used to show *inherent robust stability* to system's disturbances and measurement errors. Therefore, we can confidently

state that well-designed distributed cooperative MPC and centralized MPC algorithms share the *same guarantees* in terms of stability and robustness.

Complementary Aspects

We discuss in this section a number of complementary aspects of distributed MPC algorithms, omitting technical details for the sake of space.

Coupled Input Constraints and State Constraints

Convergence of the solution of cooperative distributed MPC towards the centralized (global) optimum holds when input constraints are in the form of (3), i.e., when no constraints involve inputs of different subsystems. Sometimes this assumption fails to hold, e.g., when several units share a common utility resource, that is, in addition to (3) some constraints involve inputs of more than one unit. In this situation, it is possible that Algorithm 1 remains stuck at a fixed point, without improving the cost, even if it is still away from the centralized optimum (Rawlings and Mayne 2009, §6.3.2). It is important to point out that this situation is harmless from a closed-loop stability and robustness point of view. However, the degree of suboptimality in comparison with centralized MPC could be undesired from a performance point of view. To overcome this situation, a slightly different partitioning of the overall inputs into non-disjoint sets can be adopted (Stewart et al. 2010).

Similarly the presence of state constraints, even in decentralized form $x_i \in \mathbb{X}_i$ (with $i = 1, \ldots, M$), can prevent convergence of a cooperative algorithm towards the centralized optimum. It is also important to point out that the local MPC controlling $\mathbb{S}_i$ needs to consider in the optimal control problem, besides local state constraints $x_i \in \mathbb{X}_i$, also state constraints of all other subsystems $\mathbb{S}_j$ such that $i \in \mathcal{N}_j$. This ensures feasibility of each iterate and cost reduction, hence closed-loop stability (and robustness) can be established.

Output Feedback and Offset-Free Tracking

When the subsystem state cannot be directly measured, each local controller can use a local state estimator, namely, a Kalman filter (or Luenberger observer). Assuming that the pair (A_i, C_i) is detectable, the subsystem state estimate evolves as follows:

$$\hat{x}_i^+ = A_i \hat{x}_i + B_i u_i + \sum_{j \in \mathcal{N}_i} B_{ij} u_j + L_i(y_i - C_i \hat{x}_i) \tag{12}$$

in which $L_i \in \mathbb{R}^{n_i \times p_i}$ is the local Kalman predictor gain, chosen such that the matrix $(A_i - L_i C_i)$ is Schur. Stability of the closed-loop origin can be still established using minor variations (Rawlings and Mayne 2009, §6.3.3).

When offset-free control is sought, each local MPC can be equipped with an integrating disturbance model similarly to centralized offset-free MPC algorithms (Pannocchia and Rawlings 2003). Given the current estimate of the subsystem state and disturbance, a target calculation problem is solved to compute the state and input equilibrium pair such that (a subset of) output variables correspond to given set points. Such a target calculation problem can be performed in a centralized fashion or in a distributed manner, although in the latter case several issues arise and associated precautions should be taken into account (Rawlings and Mayne 2009, §6.3.4).

Distributed Control for Nonlinear Systems

Several nonlinear distributed MPC algorithms have been recently proposed (Liu et al. 2009; Stewart et al. 2011). Some schemes require the presence of a coordinator, thus introducing a hierarchical structure (Scattolini 2009). In Stewart et al. (2011), instead, a cooperative distributed MPC architecture similar to the one discussed in the previous section has been proposed for nonlinear systems. Each local controller considers the following subsystem model:

$$\begin{aligned} x_i^+ &= f_i(x_i, u_i, u_j), \quad \text{with } j \in \mathcal{N}_i \\ y_i &= h_i(x_i) \end{aligned} \tag{13}$$

A problem (formally) identical to $\mathbb{P}_i^{\text{CDi}}$ in (9) is solved by each controller and cooperative iterations are performed. However, non-convexity of $\mathbb{P}_i^{\text{CDi}}$ can make a convex combination step similar to Step 8 in Algorithm 1 not necessarily a cost improvement. As a workaround in such cases, Stewart et al. (2011) propose deleting the least effective control sequence computed by a local controller (repeating this deletion if necessary). In this way it is possible to show a monotonic decrease of the cost function at each cooperative iteration.

Summary and Future Directions

We presented the basics and foundations of distributed model predictive control (DMPC) schemes, which prove useful and effective in the control of large-scale systems for which a single centralized predictive controller is not regarded as a possible or desirable solution, e.g., due to organizational requirements and/or computational limitations. In DMPCs, the overall controlled system is organized into a number of subsystems, in general featuring some dynamic couplings, and for each subsystem a local MPC is implemented.

Different flavors of communication and cooperation among the local controllers can be chosen by the designer, ranging from *decentralized* to *cooperative* schemes. In cooperative DMPC algorithms, the dynamic interactions among the subsystems are fully taken into account, with limited communication overheads, and the same overall objective can be optimized by each local controller. When cooperative iterations are performed upon convergence, such DMPC algorithms achieve the same global minimum control sequence as that of the centralized MPC. Termination prior to convergence does not hinder stability and robustness guarantees.

In this contribution, after discussing an overview on possible communication and cooperation schemes, we addressed the design of a state-feedback and distributed MPC algorithm for linear systems subject to input constraints, with convergence and stability guarantees. Then,

we discussed various extensions to coupled input constraints and state constraints, output feedback, reference target tracking, and nonlinear systems.

The research on DMPC algorithms has been extensive during the last decade, and some excellent review papers have been recently made available (Christofides et al. 2013; Scattolini 2009). Still, we expect DMPC to attract research efforts in various directions, as briefly discussed:

- *Nonlinear DMPC* algorithms (Liu et al. 2009; Stewart et al. 2011) will require improvements in terms of global optimum goals.
- *Economic DMPC* and *tracking DMPC* (Ferramosca et al. 2013) will replace current formulations designed for regulation around the origin, especially for nonlinear systems.
- *Reconfigurability*, e.g., addition/deletion of new local controllers, is an ongoing topic, and preliminary results available for decentralized architectures (Riverso et al. 2013) may be extended to cooperative and noncooperative schemes. It is also desirable to improve the resilience of DMPC to *communication disruptions* (Alessio et al. 2011).
- Preliminary results on *constrained distributed estimation* (Farina et al. 2012) will draw attention and require further insights to bridge the gap between constrained estimation and control algorithms.
- Specific *optimization algorithms* tailored to DMPC local problems (Doan et al. 2011) will increase the effectiveness of DMPC algorithms, as well as *distributed optimization* approaches will be exploited even for dynamically uncoupled systems.

Distributed Optimization

Angelia Nedić
Industrial and Enterprise Systems Engineering, University of Illinois, Urbana, IL, USA

Abstract

The paper provides an overview of the distributed first-order optimization methods for solving a constrained convex minimization problem, where the objective function is the sum of local objective functions of the agents in a network. This problem has gained a lot of interest due to its emergence in many applications in distributed control and coordination of autonomous agents and distributed estimation and signal processing in wireless networks.

Keywords

Collaborative multi-agent systems; Consensus protocol; Gradient-projection method; Networked systems

Introduction

There has been much recent interest in distributed optimization pertinent to optimization aspects arising in control and coordination of networks consisting of multiple (possibly mobile) agents and in estimation and signal processing in sensor networks (Bullo et al. 2009; Hendrickx 2008; Kar and Moura 2011; Martinoli et al. 2013; Mesbahi and Egerstedt 2010; Olshevsky 2010). In many of these applications, the network system goal is to optimize a global objective

through local agent-based computations and local information exchange with immediate neighbors in the underlying communication network. This is motivated mainly by the emergence of large-scale data and/or large-scale networks and new networking applications such as mobile ad hoc networks and wireless sensor networks, characterized by the lack of centralized access to information and time-varying connectivity. Control and optimization algorithms deployed in such networks should be completely distributed (relying only on local observations and information), robust against unexpected changes in topology (i.e., link or node failures) and against unreliable communication (noisy links or quantized data) (see ▶ Networked Systems). Furthermore, it is desired that the algorithms are scalable in the size of the network.

Generally speaking, the problem of distributed optimization consists of three main components:

1. The optimization problem that the network of agents wants to solve collectively (specifying an objective function and constraints)
2. The local information structure, which describes what information is locally known or observable by each agent in the system (who knows what and when)
3. The communication structure, which specifies the connectivity topology of the underlying communication network and other features of the communication environment

The algorithms for solving such global network problems need to comply with the distributed knowledge about the problem among the agents and obey the local connectivity structure of the communication network (▶ Networked Systems; ▶ Graphs for Modeling Networked Interactions).

Networked System Problem

Given a set $N = \{1, 2, \ldots, n\}$ of agents (also referred to as nodes), the global system problem has the following form:

$$
\begin{aligned}
\text{minimize} \quad & \sum_{i=1}^{n} f_i(x) \\
\text{subject to} \quad & x \in X.
\end{aligned}
\tag{1}
$$

Each $f_i : \mathrm{R}^d \to \mathrm{R}$ is a convex function which represents the local objective of agent i, while $X \subseteq \mathrm{R}^d$ is a closed convex set. The function f_i is a private function known only to agent i, while the set X is commonly known by all agents $i \in N$. The vector $x \in X$ represents a global decision vector which the agents want to optimize using local information. The problem is a simple constrained convex optimization problem, where the global objective function is given by the sum of the individual objective functions $f_i(x)$ of the agents in the system. As such, the objective function is the sum of non-separable convex functions corresponding to multiple agents connected over a network.

As an example, consider the problem arising in support vector machines (SVMs), which are a popular tool for classification problems. Each agent i has a set $S_i = \left\{ \left(a_j^{(i)}, b_j^{(i)} \right) \right\}_{j=1}^{m_i}$ of m_i sample-label pairs, where $a_j^{(i)} \in \mathrm{R}^d$ is a data point and $b_j^{(i)} \in \{+1, -1\}$ is its corresponding (correct) label. The number m_i of data points for every agent i is typically very large (hundreds of thousands). Without sharing the data points, the agents want to collectively find a hyperplane that separates all the data, i.e., a hyperplane that separates (with a maximal separation distance) the data with label 1 from the data with label -1 in the global data set $\bigcup_{i=1}^{n} S_i$. Thus, the agents need to solve an unconstrained version of the problem (1), where the decision variable $x \in \mathrm{R}^d$ is a hyperplane normal and the objective function f_i of agent i is given by

$$
f_i(x) = \frac{\lambda}{2} \|x\|^2 + \sum_{j=1}^{m_i} \max \left\{ 0, 1 - b_j^{(i)} \left(x' a_j^{(i)} \right) \right\},
$$

where λ is a regularization parameter (common to all agents).

The network communication structure is represented by a directed (or undirected) graph $G = (N, E)$, with the vertex set N and the edge set E. The network is used as a medium to diffuse

the information from an agent to every other agent through local agent interactions over time (▶ Graphs for Modeling Networked Interactions). To accommodate the information spread through the entire network, it is typically assumed that the network communication graph $G = (N, E)$ is strongly connected (▶ Dynamic Graphs, Connectivity of). In the graph, a link (i, j) means that agent $i \in N$ receives the relevant information from agent $j \in N$.

Distributed Algorithms

The algorithms for solving problem (1) are constructed by using standard optimization techniques in combination with a mechanism for information diffusion through local agent interactions. A control point of view for the design of distributed algorithms has a nice exposition in Wang and Elia (2011).

One of the existing optimization techniques is the so-called incremental method, where the information is processed along a directed cycle in the graph. In this approach the estimate is passed from an agent to its neighbor (along the cycle), and only one agent updates at a time (Bertsekas 1997; Blatt et al. 2007; Johansson 2008; Johansson et al. 2009; Nedić and Bertsekas 2000, 2001; Nedić et al. 2001; Rabbat and Nowak 2004; Ram et al. 2009; Tseng 1998); for a detailed literature on incremental methods, see the textbooks Bertsekas (1999) and Bertsekas et al. (2003).

More recently, one of the techniques that gained popularity as a mechanism for information diffusion is a consensus protocol, in which the agent diffuses the information through the network through locally weighted averaging of their incoming data (▶ Averaging Algorithms and Consensus). The problem of reaching a consensus on a particular scalar value, or computing exact averages of the initial values of the agents, has gained an unprecedented interest as a central problem inherent to cooperative behavior in networked systems (Blondel et al. 2005; Boyd et al. 2005; Cao et al. 2005, 2008a,b; Jadbabaie et al. 2003; Olfati-Saber and Murray

2004; Olshevsky 2010; Olshevsky and Tsitsiklis 2006, 2009; Touri 2011; Vicsek et al. 1995; Wan and Lemmon 2009).

Using the consensus technique, a class of distributed algorithms has emerged, as a combination of the consensus protocols and the gradient-type methods. The gradient-based approaches are particularly suitable, as they have a small overhead per iteration and are, in general, robust to various sources of errors and uncertainties.

The technique of using the network as a medium to propagate the relevant information for optimization purpose has its origins in the work by Tsitsiklis (1984), Tsitsiklis et al. (1986), and Bertsekas and Tsitsiklis (1997), where the network has been used to decompose the vector x components across different agents, while all agents share the same objective function.

Algorithms Using Weighted Averaging

The technique has recently been employed in Nedić and Ozdaglar (2009) (see also Nedić and Ozdaglar 2007, 2010) to deal with problems of the form (1) when the agents have different objective functions f_i, but their decisions are fully coupled through the common vector variable x. In a series of recent work (to be detailed later), the following distributed algorithm has emerged. Letting $x_i(k) \in X$ be an estimate (of the optimal decision) at agent i and time k, the next iterate is constructed through two updates. The first update is a consensus-like iteration, whereby, upon receiving the estimates $x_j(k)$ from its (in)neighbors j, the agent i aligns its estimate with its neighbors through averaging, formally given by

$$v_i(k) = \sum_{j \in N_i} w_{ij} x_j(k), \qquad (2)$$

where N_i is the neighbor set

$$N_i = \{j \in N | (j, i) \in E\} \cup \{i\}.$$

The neighbor set N_i includes agent i itself, since the agent always has access to its own information. The scalar w_{ij} is a nonnegative weight that

agent i places on the incoming information from neighbor $j \in N_i$. These weights sum to 1, i.e., $\sum_{j \in N_i} w_{ij} = 1$, thus yielding $v_i(k)$ as a (local) convex combination of $x_j(k)$, $j \in N_i$, obtained by agent i.

After computing $v_i(k)$, agent i computes a new iterate $x_i(k + 1)$ by performing a gradient-projection step, aimed at minimizing its own objective f_i, of the following form:

$$x_i(k + 1) = \prod_X \left[v_i(k) - \alpha(k) \nabla f_i(v_i(k)) \right], \tag{3}$$

where $\Pi_X[x]$ is the projection of a point x on the set X (in the Euclidean norm), $\alpha(k) > 0$ is the stepsize at time k, and $\nabla f_i(z)$ is the gradient of f_i at a point z.

When all functions are zero and X is the entire space P^d, the distributed algorithm (2) and (3) reduces to the linear-iteration method:

$$x_i(k + 1) = \sum_{j \in N_i} w_{ij} x_j(k), \tag{4}$$

which is known as *consensus* or *agreement protocol*. This protocol is employed when the agents in the network wish to align their decision vectors $x_i(k)$ to a common vector $\hat{x}$. The alignment is attained asymptotically (as $k \to \infty$).

In the presence of objective function and constraints, the distributed algorithm in (2) and (3) corresponds to "forced alignment" guided by the gradient forces $\sum_{i=1}^n \nabla f_i(x)$. Under appropriate conditions, the alignment is forced to a common vector x^* that minimizes the network objective $\sum_{i=1}^n f_i(x)$ over the set X. This corresponds to the convergence of the iterates $x_i(k)$ to a common solution $x^* \in X$ as $k \to \infty$ for all agents $i \in N$.

The conditions under which the convergence of $\{x_i(k)\}$ to a common solution $x^* \in X$ occurs are a combination of the conditions needed for the consensus protocol to converge and the conditions imposed on the functions f_i and the stepsize $\alpha(k)$ to ensure the convergence of standard gradient-projection methods. For the consensus part, the conditions should guarantee that the pure consensus protocol in (4) converges to the average $\frac{1}{n} \sum_{i=1}^n x_i(0)$ of the initial agent values. This requirement transfers to the condition that

the weights w_{ij} give rise to a doubly stochastic weight matrix W, whose entries are w_{ij} defined by the weights in (4) and augmented by $w_{ij} = 0$ for $j \notin N_i$.

Intuitively, the requirement that the weight matrix W is doubly stochastic ensures that each agent has the same influence on the system behavior, in a long run. More specifically, the doubly stochastic weights ensure that the system as whole minimizes $\sum_{i=1}^n \frac{1}{n} f_i(x)$, where the factor $1/n$ is seen as portion of the influence of agent i. When the weight matrix W is only row stochastic, the consensus protocol converges to a weighted average $\sum_{i=1}^n \pi_i x_i(0)$ of the agent initial values, where π is the left eigenvector of W associated with the eigenvalue 1. In general, the values π_i can be different for different indices i, and the distributed algorithm in (2) and (3) results in minimizing the function $\sum_{i=1}^n \pi_i f_i(x)$ over X, and thus not solving problem (1).

The distributed algorithm (2) and (3) has been proposed and analyzed in Ram et al. (2010a, 2012), where the convergence had been established for diminishing stepsize rule (i.e., $\sum_k \alpha(k) = \infty$ and $\sum_k \alpha^2(k) < \infty$). As seen from the convergence analysis (see, e.g., Nedić and Ozdaglar 2009; Ram et al. 2012), for the convergence of the method, it is critical that the iterate disagreements $\| x_i(k) - x_j(k) \|$ converge linearly in time, for all $i \neq j$. This fast disagreement decay seems to be indispensable for ensuring the stability of the iterative process (2) and (3).

According to the distributed algorithm (2) and (3), at first, each agent aligns its estimate $x_i(k)$ with the estimates $x_j(k)$ that are received from its neighbors and, then, updates based on its local objective f_i which is to be minimized over $x \in X$. Alternatively, the distributed method can be constructed by interchanging the alignment step and the gradient-projection step. Such a method, while having the same asymptotic performance as the method in (2) and (3), exhibits a somewhat slower (transient) convergence behavior due to a larger misalignment resulting from taking the gradient-based updates at first. This alternative has been initially proposed independently in Lopes and Sayed (2006) (where simulation

results have been reported), in Nedić and Ozdaglar (2007, 2009) (where the convergence analysis for a time-varying networks and a constant stepsize is given), and in Nedić et al. (2008) (with the quantization effects) and further investigated in Lopes and Sayed (2008), Nedić et al. (2010), and Cattivelli and Sayed (2010). More recently, it has been considered in Lobel et al. (2011) for state-dependent weights and in Tu and Sayed (2012) where the performance is compared with that of an algorithm of the form (2) and (3) for estimation problems.

Algorithm Extensions: Over the past years, many extensions of the distributed algorithm in (2) and (3) have been developed, including the following:

(a) *Time-varying communication graphs*: The algorithm naturally extends to the case of time-varying connectivity graphs $\{G(k)\}$, with $G(k) = (N, E(k))$ defined over the node set N and time-varying links $E(k)$. In this case, the weights w_{ij} in (2) are replaced with $w_{ij}(k)$ and, similarly, the neighbor set N_i is replaced with the corresponding time-dependent neighbor set $N_i(k)$ specified by the graph $G(k)$. The convergence of the algorithm (2) and (3) with these modifications typically requires some additional assumptions of the network connectivity over time and the assumptions on the entries in the corresponding weight matrix sequence $\{W(k)\}$, where $w_{ij}(k) = 0$ for $j \notin N_i(k)$. These conditions are the same as those that guarantee the convergence of the (row stochastic) matrix sequence $\{W(k)\}$ to a rank-one row-stochastic matrix, such as a connectivity over some fixed period (of a sliding-time window), the nonzero diagonal entries in $W(k)$, and the existence of a uniform lower bound on positive entries in $W(k)$; see, for example, Cao et al. (2008b), Touri (2011), Tsitsiklis (1984), Nedić and Ozdaglar (2010), Moreau (2005), and Ren and Beard (2005).

(b) *Noisy gradients*: The algorithm in (2) and (3) works also when the gradient computations $\nabla f_i(x)$ in update (3) are erroneous with random errors. This corresponds to using a stochastic gradient $\tilde{\nabla} f_i(x)$ instead of

$\nabla f_i(x)$, resulting in the following stochastic gradient-projection step:

$$x_i(k+1) = \prod_X \left[v_i(k) - \alpha(k)\tilde{\nabla} f_i(v_i(k)) \right]$$

instead of (3). The convergence of these methods is established for the cases when the stochastic gradients are consistent estimates of the actual gradient, i.e.,

$$\mathrm{E}\left[\tilde{\nabla} f_i(v_i(k))|v_i(k) \right] = \nabla f_i(v_i(k)).$$

The convergence of these methods typically requires the use of non-summable but square-summable stepsize sequence $\{\alpha(k)\}$ (i.e., $\sum_k \alpha(k) = \infty$ and $\sum_k \alpha^2(k) < \infty$), e.g., Ram et al. (2010a).

(c) *Noisy or unreliable communication links*: Communication medium is not always perfect and, often, the communication links are characterized by some random noise process. In this case, while agent $j \in N_i$ sends its estimate $x_j(k)$ to agent i, the agent does not receive the intended message. Rather, it receives $x_j(k)$ with some random link-dependent noise $\xi_{ij}(k)$, i.e., it receives $x_j(k) + \xi_{ij}(k)$ instead of $x_j(k)$ (see Kar and Moura 2011; Patterson et al. 2009; Touri and Nedić 2009 for the influence of noise and link failure on consensus). In such cases, the distributed optimization algorithm needs to be modified to include a stepsize for noise attenuation and the standard stepsize for the gradient scaling. These stepsizes are coupled through an appropriate relative-growth conditions which ensure that the gradient information is maintained at the right level and, at the same time, link-noise is attenuated appropriately (Srivastava and Nedić 2011; Srivastava et al. 2010). Other imperfections of the communication links can also be modeled and incorporated into the optimization method, such as link failures and quantization effects, which can be built using the existing results for consensus protocol (e.g., Carli et al. 2007; Kar and Moura 2010, 2011; Nedić et al. 2008).

(d) *Asynchronous implementations*: The method in (2) and (3) has simultaneous updates,

evident in all agents exchanging and updating information in synchronous time steps indexed by k. In some communication settings, the synchronization of agents is impractical, and the agents are using their own clocks which are not synchronized but do tick according to a common time interval. Such communications result in random weights $w_{ij}(k)$ and random neighbor set $N_i(k) \subseteq E$ in (2), which are typically independent and identically distributed (over time). Most common models are random gossip and random broadcast. In the gossip model, at any time, two randomly selected agents i and j communicate and update, while the other agents sleep (Boyd et al. 2005; Kashyap et al. 2007; Ram et al. 2010b; Srivastava 2011; Srivastava and Nedić 2011). In the broadcast model, a random agent i wakes up and broadcasts its estimate $x_i(k)$. Its neighbors that receive the estimate update their iterates, while the other agents (including the agent who broadcasted) do not update (Aysal et al. 2008; Nedić 2011).

(e) *Distributed constraints*: One of the more challenging aspects is the extension of the algorithm to the case when the constraint set X in (1) is given as an intersection of closed convex sets X_i, one set per agent. Specifically, the set X in (1) is defined by

$$X = \bigcap_{i=1}^{n} X_i,$$

where the set X_i is known to agent i only. In this case, the algorithm has a slight modification at the update of $x_i(k+1)$ in (3), where the projection is on the local set X_i instead of X, i.e., the update in (3) is replaced with the following update:

$$x_i(k+1) = \prod_{X_i} \big[v_i(k) - \alpha(k) \nabla f_i(v_i(k)) \big].$$
$$(5)$$

The resulting method (2), (5) converges under some additional assumptions on the sets X_i, such as the nonempty interior assumption (i.e., the set $\bigcap_{i=1}^{n} X_i$ has a nonempty interior), a linear-intersection assumption (each

X_i is an intersection of finitely many linear equality and/or inequality constraints), or the Slater condition (Lee and Nedić 2012; Nedić et al. 2010; Srivastava 2011; Srivastava and Nedić 2011; Zhu and Martínez 2012).

In principle, most of the simple first-order methods that solve a centralized problem of the form (1) can also be distributed among the agents (through the use of consensus protocols) to solve distributed problem (1). For example, the Nesterov dual-averaging subgradient method (Nesterov 2005) can be distributed as proposed in Duchi et al. (2012), a distributed Newton-Raphson method has been proposed and studied in Zanella et al. (2011), while a distributed simplex algorithm has been constructed and analyzed in Bürger et al. (2012). An interesting method based on finding a zero of the gradient $\nabla f = \sum_{i=1}^{n} \nabla f_i$, distributedly, has been proposed and analyzed in Lu and Tang (2012). Some other distributed algorithms and their implementations can be found in Johansson et al. (2007), Tsianos et al. (2012a,b), Dominguez-Garcia and Hadjicostis (2011), Tsianos (2013), Gharesifard and Cortés (2012a), Jakovetic et al. (2011a,b), and Zargham et al. (2012).

Summary and Future Directions

The distributed optimization algorithms have been developed mainly using consensus protocols that are based on weighted averaging, also known as linear-iterative methods. The convergence behavior and convergence rate analysis of these methods combines the tools from optimization theory, graph theory, and matrix analysis. The main drawback of these algorithms is that they require (at least theoretically) the use of doubly stochastic weight matrix W (or $W(k)$ in time-varying case) in order to solve problem (1). This requirement can be accommodated by allowing agents to exchange locally some additional information on the weights that they intend to use or their degree knowledge. However, in general, constructing such doubly stochastic weights distributedly on directed graphs is rather a complex problem (Gharesifard and Cortés 2012b).

As an alternative, which seems a promising direction for future research, is the use of so-called push-sum protocol (or sum-ratio algorithm) for consensus problem (Benezit et al. 2010; Kempe et al. 2003). This direction is pioneered in Tsianos et al. (2012b), Tsianos (2013), and Tsianos and Rabbat (2011) for static graphs and recently extended to directed graphs Nedić and Olshevsky (2013) for an unconstrained version of problem (1).

Another promising direction lies in the use of alternating direction method of multipliers (ADMM) in combination with the graph-Laplacian formulation of consensus constraints $N_i x_i = \sum_{j \in N_i} x_j$. A nice exposure to ADMM method is given in Boyd et al. (2010). The first work to address the development of distributed ADMM over a network is Wei and Ozdaglar (2012), where a static network is considered. Its distributed implementation over time-varying graphs will be an important and challenging task.

Abstract

Dynamic networks have recently emerged as an efficient way to model various forms of interaction within teams of mobile agents, such as

sensing and communication. This article focuses on the use of graphs as models of wireless communications. In this context, graphs have been used widely in the study of robotic and sensor networks and have provided an invaluable modeling framework to address a number of coordinated tasks ranging from exploration, surveillance, and reconnaissance to cooperative construction and manipulation. In fact, the success of these stories has almost always relied on efficient information exchange and coordination between the members of the team, as seen, e.g., in the case of distributed state agreement where multi-hop communication has been proven necessary for convergence and performance guarantees.

Keywords

Algebraic graph theory; Convex optimization; Distributed and hybrid control; Graph connectivity

Introduction

Communication in networked dynamical systems has typically relied on constructs from graph theory, with disc-based and weighted-proximity graphs gaining the most popularity; see Fig. 1a, b. Besides their simplicity, these models owe their popularity to their resemblance to radio signal strength models, where the signals attenuate with the distance (Neskovic et al. 2000; Pahlavan and Levesque 1995; Parsons 2000). In this context, multi-hop communication becomes equivalent to network connectivity, defined as the property of a graph to transmit information between any pair of its nodes; see Fig. 1c.

Specifically, let $\mathcal{G}(t) = \{\mathcal{V}, \mathcal{E}(t), \mathcal{W}(t)\}$ denote a graph on n nodes that can be robots or mobile sensors, so that $\mathcal{V} = \{1, \ldots, n\}$ is the set of vertices, $\mathcal{E}(t) \subseteq \mathcal{V} \times \mathcal{V}$ is the set of edges at time t, and $\mathcal{W}(t) = \{w_{ij}(t) \mid (i, j) \in \mathcal{V} \times \mathcal{V}\}$ is a set of weights so that $w_{ij}(t) = 0$ if $(i, j) \notin \mathcal{E}(t)$ and $w_{ij}(t) > 0$ otherwise. If $w_{ij}(t) = w_{ji}(t)$ for all pairs of nodes i, j, then the graph is called
Dynamic Graphs, Connectivity of, Fig. 1 (**a**) Disc-based model of communication; (**b**) Weighted, proximity-based model of communication; (**c**) Connected network of mobile robots

undirected; otherwise it is called directed. The weights in $\mathcal{W}(t)$ typically model signal strength or channel reliability, as per the disc-based and weighted-proximity models in Fig. 1a, b. In these models communication between nodes is related to their pairwise distance, giving rise to the dynamic or time-varying nature of the graph $\mathcal{G}(t)$ due to node mobility. Given an undirected dynamic graph $\mathcal{G}(t)$, we say that this graph is *connected* at time t if there exists a path, i.e., a sequence of distinct vertices such that consecutive vertices are adjacent, between any two vertices in $\mathcal{G}(t)$. In the case of directed graphs, two notions of connectivity are defined. A directed graph $\mathcal{G}(t)$ is called *strongly connected* if there exists a directed path between any two of its vertices or equivalently, if every vertex is reachable from any other vertex. On the other hand, a directed graph is called *weakly connected* if replacing all directed edges by undirected edges produces a connected undirected graph. Finally, a collection of graphs $\{\mathcal{G}(t) \mid t = t_0, \ldots, t_k\}$ is called *jointly connected* over time if the union graph $\cup_{t=t_0}^{t_k} \mathcal{G}(t) = \{\mathcal{V}, \cup_{t=t_0}^{t_k} \mathcal{E}(t)\}$ is connected. Clearly checking for the existence of paths between all pairs of nodes in a graph is difficult, especially so as the number of nodes in the graph increases. For this reason, equivalent, algebraic representations of graphs are employed that allow for efficient algebraic ways to check for connectivity, as we discuss in the following section.

While connectivity is necessary for information propagation in a network, it is also relevant to the performance of many networked dynamical processes, such as synchronization and gossiping, via its relation to the network eigenvalue spectra (Preciado 2008). For example, the spectrum of the Laplacian matrix of a network plays a key role in the analysis of synchronization in networks of nonlinear oscillators (Pecora and Carrollg 1998; Preciado and Verghese 2005), distributed algorithms (Lynch 1997), and decentralized control problems (Fax and Murray 2004; Olfati Saber and Murray 2004). Similarly, the spectrum of the adjacency matrix determines the speed of viral information spreading in a network (Van Mieghem et al. 2009). Additionally, more robust versions of connectivity, such as *k-node* or *k-edge* connectivity, can be used to introduce robustness of a network to node or link failures, respectively (Zavlanos and Pappas 2005, 2008).

Graph-Theoretic Connectivity Control

Connectivity Using the Graph Laplacian Matrix

A metric that is typically employed to capture connectivity of dynamic networks is the second smallest eigenvalue $\lambda_2(L)$ of the Laplacian matrix $L \in \mathbb{R}^{n \times n}$ of the graph, also known as the algebraic connectivity or Fiedler value of the graph. For a weighted graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}, \mathcal{W}\}$, the entries of the Laplacian matrix are typically related to the weights in $\mathcal{W}$ so that the i, j entry of L is given by $[L]_{ij} = \sum_{j=1}^{n} w_{ij}$ if $i = j$ and $[L]_{ij} = -w_{ij}$ if $i \neq j$. The Laplacian matrix of an undirected graph is always a symmetric, positive semidefinite matrix whose smallest eigenvalue $\lambda_1(L)$ is identically zero

with corresponding eigenvector the vector of all entries equal to one. Additionally, the algebraic connectivity $\lambda_2(L)$ is a concave function of the Laplacian matrix that is positive if and only if the graph is connected (Fiedler 1973; Godsil and Royle 2001; Merris 1994; Mohar 1991).

As the algebraic connectivity $\lambda_2(L)$ plays a critical role in determining whether a graph is connected or not, a number of methods have been proposed for its decentralized estimation and control. These range from methods that employ market-based control to underestimate the algebraic connectivity and accordingly control the network structure (Zavlanos and Pappas 2008) to methods that enforce the states of the nodes to oscillate at frequencies that correspond to the Laplacian eigenvalues and then use fast Fourier transform to estimate these eigenvalues (Franceschelli et al. 2013), to methods that iteratively update the interval where the algebraic connectivity is supposed to lie (Montijano et al. 2011), and to methods that rely on the power iteration method and its variants (DeGennaro and Jadbabaie 2006; Kempe and McSherry 2008; Knorn et al. 2009; Oreshkin et al. 2010; Sabattini et al. 2011; Yang et al. 2010). All the above techniques are often integrated with appropriate controllers to regulate mobility of the nodes while ensuring connectivity of the network. Another way that $\lambda_2(L)$ can be used to ensure connectivity of dynamic graphs is via optimization-based methods that maximize it away from its zero value. Such approaches were initially centralized as connectivity is a global property of a graph (Kim and Mesbahi 2006), although recently distributed subgradient algorithms (DeGennaro and Jadbabaie 2006) as well as non-iterative decomposition techniques (Simonetto et al. 2013) have also been proposed. As the algebraic connectivity is a non-differentiable function of the Laplacian matrix, designing continuous feedback controllers to maintain it positive definite is a challenging task. This problem was overcome in Zavlanos and Pappas (2007) via the use of gradient flows that maintain positive definiteness of the determinant of the projected Laplacian matrix to the space that is perpendicular to eigenvector of ones.

Connectivity Using the Graph Adjacency Matrix

Alternatively, connectivity can be captured by the sum of powers $\sum_{k=0}^{K} A^k$ of the adjacency matrix $A \in \mathbb{R}^{n \times n}$ of the network for $K \leq n - 1$. The entries of the adjacency matrix are typically related to the weights in $\mathcal{W}$ as $[A]_{ij} = w_{ij}$. For disc-based graphs as in Fig. 1a, the i, j entry of the kth power of the adjacency matrix $[A^k]_{ij}$ captures the number of paths of length k between nodes i and j; for weighted graphs, $[A^k]_{ij}$ captures a weighted sum of those paths. Therefore, the entries of $\sum_{k=0}^{K} A^k$ represent the number of paths up to length K between every pair of nodes in the graph (Godsil and Royle 2001). By definition of graph connectivity, if all entries of $\sum_{k=0}^{K} A^k$ are positive for $K = n - 1$, then the network is connected. Clearly, for $K < n - 1$, not all entries of $\sum_{k=0}^{K} A^k$ are necessarily positive, even if the graph is connected. Maintaining positive definiteness of the positive entries of $\sum_{k=0}^{K} A^k$ of an initially connected graph maintains paths of length K between the corresponding nodes and, as shown in Zavlanos and Pappas (2005), is sufficient to maintain connectivity of the graph throughout.

The ability to capture graph connectivity using the adjacency matrix has given rise to optimization-based connectivity controllers (Srivastava and Spong 2008; Zavlanos and Pappas 2005) that are often centralized due to the multi-hop dependencies between nodes due to the powers of the adjacency matrix. Since smaller powers correspond to shorter dependencies (paths), decentralization is possible as K decreases. If $K = 1$, connectivity maintenance reduces to preserving the pairwise links between the nodes in an initially connected network. Since the adjacency matrix of weighted graphs is often a differentiable function, this approach can result in continuous feedback solution techniques. Discrete-time approaches are discussed in Ando et al. (1999), Notarstefano et al. (2006), and Bullo et al. (2009), while Spanos and Murray (2004), Dimarogonas and Kyriakopoulos (2008), Cornejo and Lynch (2008), Yao and Gupta (2009), Zavlanos et al. (2007), and Ji and Egerstedt (2007) rely on local gradients that

may also incorporate switching in the case of link additions. Switching between arbitrary spanning topologies has also been studied in the literature, with the spanning subgraphs being updated by local auctions (Zavlanos and Pappas 2008), distributed spanning tree algorithms (Wagenpfeil et al. 2009), combination of information dissemination algorithms and graph picking games (Schuresko and Cortes 2009b), or intermediate rendezvous (Schuresko and Cortes 2009a; Spanos and Murray 2005). This class of approaches is typically hybrid, combining continuous link maintenance and discrete topology control. The algebraic connectivity $\lambda_2(L)$ and number of paths $\sum_{k=0}^{K} A^k$ metrics can also be combined to give controllers that maintain connectivity, while enforcing desired multi-hop neighborhoods for all agents (Stump et al. 2008).

A recent, comprehensive survey on graph-theoretic approaches for connectivity control of dynamic graphs can be found in Zavlanos et al. (2011).

Applications in Mobile Robot Network Control

Methods to control connectivity of dynamic graphs have been successfully applied to multiple scenarios that require network connectivity to achieve a global coordinated objective. Indicative of the impact of this work is recent literature on connectivity preserving rendezvous (Ando et al. 1999; Cortes et al. 2006; Dimarogonas and Kyriakopoulos 2008; Ganguli et al. 2009; Ji and Egerstedt 2007), flocking (Zavlanos et al. 2007, 2009), and formation control (Ji and Egerstedt 2007; Schuresko and Cortes 2009a), where so far connectivity had been an assumption. Further extensions and contributions involve connectivity control for double integrator agents (Notarstefano et al. 2006), agents with bounded inputs (Ajorlou and Aghdam 2010; Ajorlou et al. 2010; Dimarogonas and Johansson 2008), and indoor navigation (Stump et al. 2008), as well as for communication based on radio signal strength (Hsieh et al. 2008; Mostofi 2009;

Powers and Balch 2004; Wagner and Arkin 2004) and visibility constraints (Anderson et al. 2003; Ando et al. 1999; Arkin and Diaz 2002; Flocchini et al. 2005; Ganguli et al. 2009). Periodic connectivity for robot teams that need to occasionally split in order to achieve individual objectives (Hollinger and Singh 2010; Zavlanos 2010) and sufficient conditions for connectivity in leader-follower networks (Gustavi et al. 2010) also adds to the list. Early experimental results have demonstrated efficiency of these algorithms also in practice (Hollinger and Singh 2010; Michael et al. 2009; Tardioli et al. 2010).

Summary and Future Directions

Although graphs provide a simple abstraction of inter-robot communications, it has long been recognized that since links in a wireless network do not entail tangible connections, associating links with arcs on a graph can be somewhat arbitrary. Indeed, topological definitions of connectivity start by setting target signal strengths to draw the corresponding graph. Even small differences in target strengths might result in dramatic differences in network topology (Lundgren et al. 2002). As a result, graph connectivity is necessary but not nearly sufficient to guarantee communication integrity, interpreted as the ability of a network to support desired communication rates.

To address these challenges, a new body of work is recently appearing that departs from traditional graph-based models of communication. Specifically, Zavlanos et al. (2013) employs a simple, yet effective, modification that relies on weighted graph models with weights that capture the packet error probability of each link (De-Couto et al. 2006). When using reliabilities as link metrics, it is possible to model routing and scheduling problems as optimization problems that accept link reliabilities as inputs (Ribeiro et al. 2007, 2008). The key idea proposed in Zavlanos et al. (2013) is to define connectivity in terms of communication rates and to use optimization formulations to describe optimal operating points of wireless networks. Then, the

communication variables are updated in discrete time via a distributed gradient descent algorithm on the dual function, while robot motion is regulated in continuous time by means of appropriate distributed barrier potentials that maintain desired communication rates. Related approaches consider optimal communications based on T-slot time averages of the primal variables for general mobility schemes Neely (2010), as well as optimization of mobility and communications based on the end-to-end bit error rate between nodes (Ghaffarkhah and Mostofi 2011; Yan and Mostofi 2012).

Dynamic Noncooperative Games

David A. Castañón
Boston University, Boston, MA, USA

Abstract

In this entry, we present models of dynamic noncooperative games, solution concepts and algorithms for finding game solutions. For the sake of exposition, we focus mostly on finite games, where the number of actions available to each player is finite, and discuss briefly extensions to infinite games.

Keywords

Extensive form games; Finite games; Nash equilibrium

Introduction

Dynamic noncooperative games allow multiple actions by individual players, and include explicit representations of the information available to each player for selecting its decision. Such games have a complex temporal order of play and an information structure that reflects uncertainty as to what individual players know when they have to make decisions. This temporal order and information structure is not evident when the game is represented as a static game between players that select strategies. Dynamic games often incorporate explicit uncertainty in outcomes, by representing such outcomes as actions taken by a random player (called chance or "Nature") with known probability distributions for selecting its actions.

We focus our exposition on models of finite games and discuss briefly extensions to infinite games at the end of the entry.

Finite Games in Extensive Form

The *extensive form* of a game was introduced by von Neumann (1928) and later refined by Kuhn (1953) to represent explicitly the order of play, the information and actions available to each player for making decisions at each of their turns, and the payoffs that players receive after a complete set of actions. Let $I = \{0, 1, \ldots, n\}$ denote the set of players in a game, where player 0 corresponds to Nature. The extensive form is represented in terms of a game tree, consisting of a rooted tree with nodes $\mathcal{N}$ and edges $\mathcal{E}$. The root node represents the initial state of the game. Nodes x in this tree correspond to positions or "states" of the game. Any non-root node with

more than one incident edge is an internal node of the tree and is a *decision* node associated with a player in the game; the root node is also a decision node. Each decision node x has a player $o(x) \in I$ assigned to select a decision from a finite set of admissible decisions $A(x)$. Using distance from the root node to indicate direction of play, each edge that follows node x corresponds to an action in $A(x)$ taken by player $p(x)$, which evolves the state of the game into a subsequent node x'.

Non-root nodes with only one incident edge are terminal nodes, which indicate the end of the game; such nodes represent outcomes of the game. The unique path from the root node to a terminal node is a called a *play* of the game. For each outcome node x, there are payoff functions $J_i(x)$ associated with each player $i \in \{1, \ldots, n\}$.

The above form represents the different players, the order in which players select actions and their possible actions, and the resulting payoffs to each player from a complete set of plays of the game. The last component of interest is to represent the information available for players to select decisions at each decision node. Due to the tree structure of the extensive form of a game, each decision node x contains exact information on all of the previous actions taken that led to state x. In games of *perfect information*, each player knows exactly the decision node x at which he/she is selecting an action. To represent imperfect information, the extensive form uses the notion of an *information set*, which represents a group of decision nodes, associated with the same player, where the information available to that player is that the game is in one of the states in that information set. Formally, let $\mathcal{N}_i \subset \mathcal{N}$ be the set of decision nodes associated with player i, for $i \in I$. Let $\mathcal{H}_i$ denote a partition of $\mathcal{N}_i$ so that, for each set $h_i^k \in \mathcal{H}_i$, we have the following properties:

- If $x, x' \in h_i^k$, then they have the same admissible actions: $A(x) = A(x')$.
- If $x, x' \in h_i^k$, then they cannot both belong to a play of the game; that is, both x and x' cannot be on a path from the root node to an outcome.

Elements h_i^k for some player i are the *information sets*. Each decision node x belongs to one and
Dynamic Noncooperative Games, Fig. 1 Illustration of game in extensive form

only one information set associated with player $p(x)$. The constraints above ensure that, for each information set, there is a unique player identified to select actions, and the set of admissible actions is unambiguously defined. Denote by $A(h_i^k)$ the set of admissible actions at information set h_i^k. The last condition is a causality condition that ensures that a player who has selected a previous decision remembers that he/she has already made that previous decision.

Figure 1 illustrates an extensive form for a two-person game. Player 1 has two actions in any play of the game, whereas player 2 has only 1 action. Player 1 starts the game at the root node a; the information set h_2^1 shows that player 2 is unaware of this action, as both nodes that descend from node a are in this information set. After player 2's action, player 1 gets to select a second action. However, the information sets h_1^2, h_1^3 indicate that player 1 recalls what earlier action he/she selected, but he/she has not observed the action of player 2. The terminal nodes indicate the payoffs to player 1 and player 2 as an ordered pair.

Strategies and Equilibrium Solutions

A pure strategy γ_i for player $i \in \{1, \ldots, n\}$ is a function that maps each information set of player i into an admissible decision. That is,

$$\gamma_i : \mathcal{H}_i \to A$$

such that $\gamma_i(h_i^k) \in A(h_i^k)$. The set of pure strategies for player i is denoted as Γ_i.

Note that pure strategies do not include actions selected by Nature. Nature's actions are selected using probability distributions over the choices available for the information sets corresponding to Nature, where the choice at each information set is made independently of other choices. For finite games, the number of pure strategies for each player is also finite. Given a tuple of pure strategies $\underline{\gamma} = (\gamma_1, \ldots, \gamma_n)$, we can define the probability of the play of the game resulting in outcome node x as $\pi(x)$, computed as follows: Each outcome node has a unique path (the play) p_{rx} from root node r. We initialize $\pi(r) = 1$ and node $n = r$. If the player at node n is Nature and the next node in p_{rx} is n', then $\pi(n') = \pi(n) * p(n, n')$, where $p(n, n')$ is the probability that Nature chooses the action that leads to n'. Otherwise, let $i = p(n)$ be the player at node n and let $h_i^k(n)$ denote the information set containing node n. Then, if $\gamma^i(h_i^k(n)) = a(n, n')$, let $\pi(n') = \pi(n)$, where $a(n, n')$ is the action in $A(n)$ that leads to n'; otherwise, set $\pi(n') = 0$. The above process is repeated letting $n' = n$, until n' equals the terminal node x. Using these probabilities, the resulting expected payoff to player i is

$$\mathcal{J}_i(\underline{\gamma}) = \sum_{x \text{ terminal}, \, x \in \mathcal{N}} \pi(x) J_i(x)$$

This representation of payoffs in terms of strategies transforms the game from an extensive form representation to a strategic or normal form representation, where the concept of dynamics and information has been abstracted away. The resulting strategic form looks like a static game as discussed in the encyclopedia entry ▸ Strategic Form Games and Nash Equilibrium, where each player selects his/her strategy from a finite set, resulting in a vector of payoffs for the players. Using these payoffs, one can now define solution concepts for the game. Let the notation $\underline{\gamma}_{-i} = (\gamma_1, \ldots, \gamma_{i-1}, \gamma_{i+1}, \gamma_n)$ denote the set of strategies in a tuple excluding the ith strategy.

A Nash equilibrium solution is a tuple of feasible strategies $\underline{\gamma}^* = (\gamma_1^*, \ldots, \gamma_n^*)$ such that

$$\mathcal{J}_i(\underline{\gamma}^*) \geq \mathcal{J}_i(\underline{\gamma}_{-i}^*, \gamma_i) \text{ for all } \gamma_i \in \Gamma_i,$$
$$\text{for all } i \in \{1, \ldots, n\} \qquad (1)$$

The special case of two-person games where $\mathcal{J}_1(\underline{\gamma}) = -\mathcal{J}_2(\underline{\gamma})$ are known as zero-sum games.

As discussed in the encyclopedia entry on static games (▸ Strategic Form Games and Nash Equilibrium), the existence of Nash equilibria or even saddle point strategies in terms of pure strategies is not guaranteed for finite games. Thus, one must consider the use of *mixed strategies*. A mixed strategy μ_i for player $i \in \{1, \ldots, n\}$ is a probability distribution over the set of pure strategies Γ_i. The definition of payoffs can be extended to mixed strategies by averaging the payoffs associated with the pure strategies, as

$$\mathcal{J}_i(\underline{\mu}_i) = \sum_{\gamma_1 \in \Gamma_1} \cdots \sum_{\gamma_n \in \Gamma_n} \mu_1(\gamma_1) \cdots \mu_n(\gamma_n)$$
$$\mathcal{J}_i(\gamma_1, \ldots, \gamma_n)$$

Denote the set of probability distributions over Γ_i as $\Delta(\Gamma_i)$. An n-tuple $\underline{\mu}^* = (\mu_1, \ldots, \mu_n)$ of mixed strategies is said to be a Nash equilibrium if

$$\mathcal{J}_i(\underline{\mu}^*) \geq \mathcal{J}_i(\underline{\mu}_{-i}^*, \mu_i) \text{ for all } \mu_i$$
$$\in \Delta(\Gamma_i), \text{ for all } i \in \{1, \ldots, n\}$$

Theorem 1 (Nash 1950, 1951) *Every finite n-person game has at least one Nash equilibrium point in mixed strategies.*

Mixed strategies suggest that each player's randomization occurs before the game is played, by choosing a strategy at random from its choices of pure strategies. For games in extensive form, one can introduce a different class of strategies where a player makes a random choice of action at each information set, according to a probability distribution that depends on the specific information set. The choice of action is selected independently at each information set according

to a selected probability distribution, in a manner similar to how Nature's actions are selected. These random choice strategies are known as *behavior strategies*. Let $\Delta(A(h_i^k))$ denote the set of probability distributions over the decisions $A(h_i^k)$ for player i at information set h_i^k. A behavior strategy for player i is an element $x_i \in \prod_{h_i^k \in \mathcal{H}_i} \Delta(A(h_i^k))$, where $x_i(h_i^k)$ denotes the probability distribution of the behavior strategy x_i over the available decisions at information set h_i^k.

Note that the space of admissible behavior strategies is much smaller than the space of admissible mixed strategies. To illustrate this, consider a player with K information sets and two possible decisions for each information set. The number of possible pure strategies would be 2^K, and thus the space of mixed strategies would be a probability simplex of dimension $2^K - 1$. In contrast, behavior strategies would require specifying probability distributions over two choices for each of K information sets, so the space of behavior strategies would be a product space of K probability simplices of dimension 1, totaling dimension K. One way of understanding this difference is that mixed strategies introduce correlated randomization across choices at different information sets, whereas behavior strategies introduce independent randomization across such choices.

For every behavior strategy, one can find an equivalent mixed strategy by computing the probabilities of every set of actions that result from the behavior strategy. The converse is not true for general games in extensive form. However, there is a special class of games for which the converse is true. In this class of games, players recall what actions they have selected previously and what information they knew previously. A formal definition of perfect recall is beyond the scope of this exposition but can be found in Hart (1991) and Kuhn (1953). The implication of perfect recall is summarized below:

Theorem 2 (Kuhn 1953) *Given a finite n-person game in which player i has perfect recall, for each mixed strategy μ_i for player i, there exists a corresponding behavior strategy x_i that*

is equivalent, where every player receives the same payoffs under both strategies μ_i and x_i.

This equivalence was extended by Aumann to infinite games (Aumann 1964). In dynamic games, it is common to assume that each player has perfect recall and thus solutions can be found in the smaller space of behavior strategies.

Computation of Equilibria

Algorithms for the computation of mixed-strategy Nash equilibria of static games can be extended to compute mixed-strategy Nash equilibria for games in extensive form when the pure strategies are enumerated as above. However, the number of pure strategies grows exponentially with the size of the extensive form tree, making these methods hard to apply. For two-person games in extensive form with perfect recall by both players, one can search for Nash equilibria in the much smaller space of behavior strategies. This was exploited in Koller et al. (1996) to obtain efficient linear complementarity problems for nonzero-sum games and linear programs for zero-sum games where the number of variables involved is linear in the number of internal decision nodes of the extensive form of the game. A more detailed overview of computation algorithms for Nash equilibria can be found in McKelvey and McLennan (1996). The Gambit Web site (McKelvey et al. 2010) provides software implementations of several techniques for computation of Nash equilibria in two- and n-person games.

An alternative approach to computing Nash equilibria for games in extensive forms is based on subgame decomposition, discussed next.

Subgames

Consider a game G in extensive form. A node c is a successor of a node n if there is a path in the game tree from n to c. Let h be a node in G that is not terminal and is the only node in its information set. Assume that if a node c is a successor of h, then every node in the information set containing c is also a successor of h. In this situation, one can define a subgame H of G with root node h, which consists of node h and
Dynamic Noncooperative Games, Fig. 2 Simple game with multiple Nash equilibria

its successors, connected by the same actions as in the original game G, with the payoffs and terminal vertices equal to those in G. This is the subgame that would be encountered by the players had the previous play of the game reached the state at node h. Since the information set containing node h contains no other node and all the information sets in the subgame contain only nodes in the subgame, then every player in the subgame knows that they are playing only in the subgame once h has been reached.

Figure 2 illustrates a game where every non-terminal node is contained in its own information set. This game contains a subgame rooted at node c. Note that the full game has two Nash equilibria in pure strategies: strategies (L, L) and (R, R). However, strategy (L, L) is inconsistent with how player 2 would choose its decision if it were to find itself at node c. This inconsistency arises because the Nash equilibria are defined in terms of strategies announced before the game is played and may not be a reasonable way to select decisions if unanticipated plays occur. When player 1 chooses L, node c should not be reached in the play of the game, and thus player 2 can choose L because it does not affect the expected payoff. One can define the concept of Nash equilibria that are sequentially consistent as follows.

Let x_i be behavior strategies for player i in game G. Denote the restriction of these strategies to the subgame H as x_i^H. This restriction describes the probabilities for choices of actions

for the information sets in H. Suppose the game G has a Nash equilibrium achieved by strategies $(x_1, \ldots, x_n)$. This Nash equilibrium is called *subgame perfect* (Selten 1975) if, for every subgame H of G, the strategies $(x_1^H, \ldots, x_n^H)$ are a Nash equilibrium for the subgame H. In the game in Fig. 2, there is only one subgame perfect equilibrium, which is (R, R). There are several other refinements of the Nash equilibrium concept to enforce sequential consistency, such as sequential equilibria (Kreps and Wilson 1982).

An important application of subgames is to compute subgame perfect equilibria by backward induction. The idea is to start with a subgame root node as close as possible to an outcome node (e.g., node c in Fig. 2). This small subgame can be solved for its Nash equilibria, to compute the equilibrium payoffs for each player. Then, in the original game G, the root node of the subgame can be replaced by an outcome node, with payoffs equal to the equilibrium payoffs in the subgame. This results in a smaller game, and the process can be applied inductively until the full game is solved. The subgame perfect equilibrium strategies can then be computed as the solution of the different subgames solved in this backward induction process. For Fig. 2, the subgame at c is solved by player 2 selecting R, with payoffs $(4, 1)$. The reduced new game has two choices for player 1, with best decision R. This leads to the overall subgame perfect equilibrium (R, R).

This backward induction procedure is similar to the dynamic programming approach to solving control problems. Backward induction was first used by Zermelo (1912) to analyze zero-sum games of perfect information such as chess. An extension of Zermelo's work by Kuhn (1953) establishes the following result:

Theorem 3 *Every finite game of perfect information has a subgame perfect Nash equilibrium in pure strategies.*

This result follows because, at each step in the backward induction process, the resulting subgame consists of a choice among finite actions for a single player, and thus a pure strategy achieves the maximal payoff possible.

Infinite Noncooperative Games

When the number of options available to players is infinite, game trees are no longer appropriate representations for the evolution of the game. Instead, one uses state space models with explicit models of actions and observations. A typical multistage model for the dynamics of such games is

$$x(t + 1) = f(x(t), u_1(t), \ldots, u_n(t), w(t), t),$$
$$t = 0, \ldots, T - 1 \qquad (2)$$

with initial condition $\underline{x}(0) = w(0)$, where $x(t)$ is the state of the game at stage t, and $u_1(t), \ldots, u_n(t)$ are actions selected by players $1, \ldots, n$ at stage t, and $w(t)$ is an action selected by Nature at stage t. The space of actions for each player are restricted at each time to infinite sets $A_i(t)$ with an appropriate topological structure, and the admissible state $x(t)$ at each time belongs to an infinite set X with a topological structure. In terms of Nature's actions, for each stage t, there is a probability distribution that specifies the choice of Nature's action $w(t)$, selected independently of other actions.

Equation (2) describes a play of the game, in terms of how different actions by players at the various stages evolve the state of the game. A play of the game is thus a history $\underline{h} = (x(0), u_1(0), \ldots, u_n(0), x(1), u_1(1), \ldots, u_n(1), \ldots, x(T))$. Associated with each play of the game is a set of real-valued functions $J_i(\underline{h})$ that indicates the payoff to player i in this play. This function is often assumed to be separable across the variables in each stage.

To complete the description of the extensive form, one must now introduce the available information to each player at each stage. Define observation functions

$$y_i(t) = g_i(x(t), v(t), t), \quad i = 1, \ldots, n$$

where $y_i(t)$ takes values in observations spaces which may be finite or infinite, and $v(t)$ are selected by Nature given their probability distributions, independent of other

selections. Define the information available for player i at stage t to be $I_i(t)$, a subset of $\{y_1(0), \ldots, y_n(0), \ldots, y_1(t), \ldots, y_n(t); u_1(0), \ldots, u_n(0), \ldots, u_1(t-1), \ldots, u_n(t-1)\}$. With this notation, strategies $\gamma_i(t)$ for player i are functions that map, at each stage, the available information $I_i(t)$ into admissible decisions $u_i(t) \in A_i(t)$. With appropriate measurability conditions, specifying a full set of strategies $\underline{\gamma} = (\gamma_1, \ldots \gamma_n)$ for each of the players induces a probability distribution on the plays of the game, which leads to the expected payoff $\mathcal{J}_i(\underline{\gamma})$. Nash equilibria are defined in identical fashion to (1).

Obtaining solutions of multistage games is a difficult task that depends on the ability to use the subgame decomposition techniques discussed previously. Such subgame decompositions are possible when games do not include actions by Nature and the payoff functions have a stagewise additive property. Under such cases, backward induction allows the construction of Nash equilibrium strategies through the recursive solutions of static infinite games, such as those discussed in the encyclopedia entry on static games.

Generalizations of multistage games to continuous time result in differential games, covered in two articles in the encyclopedia, but for the zero-sum case. Additional details on infinite dynamic noncooperative games, exploiting different models and information structures and studying the existence, uniqueness, or nonuniqueness of equilibria, can be found in Basar and Olsder (1982).

Conclusions

In this entry, we reviewed models for dynamic noncooperative games that incorporate temporal order of play and uncertainty as to what individual players know when they have to make decisions. Using these models, we defined solution concepts for the games and discussed algorithms for determining solution strategies for the players. Active directions of research include development of new solution concepts for dynamic games, new approaches to computation of game solutions, the study of games with a large

number of players, evolutionary games where players' greedy behavior evolves toward equilibrium strategies, and special classes of dynamic games such as Markov games and differential games. Several of these topics are discussed in other entries in the encyclopedia.

Dynamic Positioning Control Systems for Ships and Underwater Vehicles

Asgeir J. Sørensen
Department of Marine Technology, Centre for Autonomous Marine Operations and Systems (AMOS), Norwegian University of Science and Technology, NTNU, Trondheim, Norway

Abstract

In 2012 the fleet of dynamically positioned (DP) ships and rigs was probably larger than 3,000 units, predominately operating in the offshore oil and gas industry. The complexity and functionality vary subject to the targeted marine operation, vessel concept, and risk level. DP systems with advanced control functions and redundant sensor, power, and thruster/propulsion configurations are designed in order to provide high-precision fault-tolerant control in safety-critical marine operations. The DP system is customized for the particular application with integration to other control systems, e.g., power management, propulsion, drilling, oil and gas production, offloading, crane operation, and pipe and cable laying. For underwater vehicles such as remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs), DP functionality also denoted as *hovering* is implemented on several vehicles.

Keywords

Autonomous underwater vehicles (AUVs); Fault-tolerant control; Remotely operated vehicles (ROVs)

Introduction

The offshore oil and gas industry is the dominating market for DP vessels. The various offshore applications include offshore service

vessels, drilling rigs (semisubmersibles) and ships, shuttle tankers, cable and pipe layers, floating production, storage, and off-loading units (FPSOs), crane and heavy lift vessels, geological survey vessels, rescue vessels, and multipurpose construction vessels. DP systems are also installed on cruise ships, yachts, fishing boats, navy ships, tankers, and others.

A DP vessel is by the International Maritime Organization (IMO) and the maritime class societies (DNV GL, ABS, LR, etc.) defined as *a vessel that maintains its position and heading (fixed location denoted as stationkeeping or predetermined track) exclusively by means of active thrusters*. The DP system as defined by class societies is not only limited to the DP control system including computers and cabling. Position reference systems of various types measuring North-East coordinates (satellites, hydroacoustic, optics, taut wire, etc.), sensors (heading, roll, pitch, wind speed and direction, etc.), the power system, thruster and propulsion system, and independent joystick system are also essential parts of the DP system. In addition, the DP operator is an important element securing safe and efficient DP operations. Further development of human-machine interfaces, alarm systems, and operator decision support systems is regarded as top priority bridging advanced and complex technology to safe and efficient marine operations. Sufficient DP operator training is a part of this.

The thruster and propulsion system controlled by the DP control system is regarded as one of the main power consumers on the DP vessel. An important control system for successful integration with the power plant and the other power consumers such as drilling system, process system, heating, and ventilation system is the power and energy management system (PMS/EMS) balancing safety requirements and energy efficiency. The PMS/EMS controls the power generation and distribution and the load control of heavy power consumers. In this context both transient and steady-state behaviors are of relevance. A thorough understanding of the hydrodynamics, dynamics between coupled systems, load characteristics of the various power consumers, control system architecture, control layers, power

system, propulsion system, and sensors is important for successful design and operation of DP systems and DP vessels.

Thruster-assisted position mooring is another important stationkeeping application often used for FPSOs, drilling rigs, and shuttle tanker operations where the DP system has to be redesigned accounting for the effect of the mooring system dynamics. In thruster-assisted position mooring, the DP system is renamed to position mooring (PM) system. PM systems have been commercially available since the 1980s. While for DP-operated ships the thrusters are the sole source of the stationkeeping, the assistance of thrusters is only complementary to the mooring system. Here, most of the stationkeeping is provided by a deployed anchor system. In severe environmental conditions, the thrust assistance is used to minimize the vessel excursions and line tension by mainly increasing the damping in terms of velocity feedback control and adding a bias force minimizing the mean tensions of the most loaded mooring lines. Modeling and control of turret-anchored ships are treated in Strand et al. (1998) and Nguyen and Sørensen (2009).

Overview of DP systems including references can be found in Fay (1989), Fossen (2011), and Sørensen (2011). The scientific and industrial contributions since the 1960s are vast, and many research groups worldwide have provided important results. In Sørensen et al. (2012), the development of DP system for ROVs is presented.

Mathematical Modeling of DP Vessels

Depending on the operational conditions, the vessel models may briefly be classified into stationkeeping, low-velocity, and high-velocity models. As shown in Sørensen (2011) and Fossen (2011) and the references therein, different model reduction techniques are used for the various speed regimes. Vessel motions in waves are defined as seakeeping and will here apply both for stationkeeping (zero speed) and forward speed. DP vessels or PM vessels can in general be regarded as stationkeeping and low-velocity or low Froude

number applications. This assumption will particularly be used in the formulation of mathematical models used in conjunction with the controller design. It is common to use a two-time scale formulation by separating the total model into a low-frequency (LF) model and a wave-frequency (WF) model (seakeeping) by superposition. Hence, the total motion is a sum of the corresponding LF and the WF components. The WF motions are assumed to be caused by first-order wave loads. Assuming small amplitudes, these motions will be well represented by a linear model. The LF motions are assumed to be caused by second-order mean and slowly varying wave loads, current loads, wind loads, mooring (if any), and thrust and rudder forces and moments.

For underwater vehicles operating below the wave zone, estimated to be deeper than half the wavelength, the wave loads can be disregarded and of course the effect of the wind loads as well.

Modeling Issues

The mathematical models may be formulated in two complexity levels:

- *Control plant model* is a simplified mathematical description containing only the main physical properties of the process or plant. This model may constitute a part of the controller. The control plant model is also used in analytical stability analysis based on, e.g., Lyapunov stability.
- *Process plant model* or simulation model is a comprehensive description of the actual process and should be as detailed as needed. The main purpose of this model is to simulate the real plant dynamics. The process plant model is used in numerical performance and robustness analysis and testing of the control systems. As shown above, the process plant models may be implemented for off-line or real-time simulation (e.g., HIL testing; see Johansen et al. 2007) purposes defining different requirements for model fidelity.

Kinematics

The relationship between the Earth-fixed position and orientation of a floating structure and its body-fixed velocities is

$$
\dot{\boldsymbol{\eta}} = \begin{bmatrix} \dot{\boldsymbol{\eta}}_1 \\ \dot{\boldsymbol{\eta}}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{J}_1(\boldsymbol{\eta}_2) & \mathbf{0}_{3\times3} \\ \mathbf{0}_{3\times3} & \mathbf{J}_2(\boldsymbol{\eta}_2) \end{bmatrix} \begin{bmatrix} \boldsymbol{v}_1 \\ \boldsymbol{v}_2 \end{bmatrix} \quad (1)
$$

The vectors defining the Earth-fixed vessel position ($\boldsymbol{\eta}_1$) and orientation ($\boldsymbol{\eta}_2$) using Euler angles and the body-fixed translation ($\boldsymbol{v}_1$) and rotation ($\boldsymbol{v}_2$) velocities are given by

$$
\boldsymbol{\eta}_1 = \begin{bmatrix} x & y & z \end{bmatrix}^T, \boldsymbol{\eta}_2 = \begin{bmatrix} \phi & \theta & \psi \end{bmatrix}^T,
$$
$$
\boldsymbol{v}_1 = \begin{bmatrix} u & v & w \end{bmatrix}^T, \boldsymbol{v}_2 = \begin{bmatrix} p & q & r \end{bmatrix}^T. \quad (2)
$$

The rotation matrix $\mathbf{J}_1(\boldsymbol{\eta}_2) \in \mathbf{SO}(3)$ and the velocity transformation matrix $\mathbf{J}_2(\boldsymbol{\eta}_2) \in \mathbb{R}^{3\times3}$ are defined in Fossen (2011). For ships, if only surge, sway and yaw (3DOF) are considered, the kinematics and the state vectors are reduced to

$$
\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi)\boldsymbol{v}, \text{ or } \begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{\psi} \end{bmatrix}
$$
$$
= \begin{bmatrix} \cos\psi & -\sin\psi & 0 \\ \sin\psi & \cos\psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} u \\ v \\ r \end{bmatrix}. \quad (3)
$$

Process Plant Model: Low-Frequency Motion

The 6-DOF LF model formulation is based on Fossen (2011) and Sørensen (2011). The equations of motion for the nonlinear LF model of a floating vessel are given by

$$
\mathbf{M}\dot{\boldsymbol{v}} + \mathbf{C}_{RB}(\boldsymbol{v})\boldsymbol{v} + \mathbf{C}_A(\boldsymbol{v}_r)\boldsymbol{v}_r + \mathbf{D}(\boldsymbol{v}_r) + \mathbf{G}(\boldsymbol{\eta})
$$
$$
= \boldsymbol{\tau}_{\text{wave2}} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{thr}} + \boldsymbol{\tau}_{\text{moor}}, \quad (4)
$$

where $\mathbf{M} \in \mathbb{R}^{6\times6}$ is the system inertia matrix including added mass; $\mathbf{C}_{RB}(\boldsymbol{v}) \in \mathbb{R}^{6\times6}$ and $\mathbf{C}_A(\boldsymbol{v}_r) \in \mathbb{R}^{6\times6}$ are the skew-symmetric Coriolis and centripetal matrices of the rigid body and the added mass; $\mathbf{G}(\boldsymbol{\eta}) \in \mathbb{R}^6$ is the generalized restoring vector caused by the mooring lines (if any), buoyancy, and gravitation; $\boldsymbol{\tau}_{\text{thr}} \in \mathbb{R}^6$ is the control vector consisting of forces and moments produced by the thruster system; $\boldsymbol{\tau}_{\text{wind}}$ and $\boldsymbol{\tau}_{\text{wave2}} \in \mathbb{R}^6$ are the wind and second-order wave load vectors, respectively.

The damping vector may be divided into linear and nonlinear terms according to

$$\mathbf{D}(\boldsymbol{v}_r) = \mathbf{d}_L(\boldsymbol{v}_r, \kappa)\boldsymbol{v}_r + \mathbf{d}_{NL}(\boldsymbol{v}_r, \gamma_r)\boldsymbol{v}_r, \quad (5)$$

where $\boldsymbol{v}_r \in \mathbb{R}^6$ is the relative velocity vector between the current and the vessel. The nonlinear damping, $\mathbf{d}_{NL}$, is assumed to be caused by turbulent skin friction and viscous eddy-making, also denoted as vortex shedding (Faltinsen 1990). The strictly positive linear damping matrix $\mathbf{d}_L \in \mathbb{R}^{6 \times 6}$ is caused by linear laminar skin friction and is assumed to vanish for increasing speed according to

$$\mathbf{d}_L(\boldsymbol{v}_r, \kappa) = \begin{bmatrix} X_{u_r} e^{-\kappa|u_r|} & .. & X_r e^{-\kappa|r|} \\ .. & .. & .. \\ N_{u_r} e^{-\kappa|u_r|} & .. & N_r e^{-\kappa|r|} \end{bmatrix}, \quad (6)$$

where κ is a positive scaling constant such that $\kappa \in \mathrm{R}^+$.

Process Plant Model: Wave-Frequency Motion

The coupled equations of the WF motions in surge, sway, heave, roll, pitch, and yaw are assumed to be linear and can be formulated as

$$\begin{aligned} \mathbf{M}(\omega)\ddot{\boldsymbol{\eta}}_{Rw} + \mathbf{D}_p(\omega)\dot{\boldsymbol{\eta}}_{Rw} + \mathbf{G}\boldsymbol{\eta}_{Rw} &= \boldsymbol{\tau}_{\text{wave1}}, \\ \dot{\boldsymbol{\eta}}_w &= \mathbf{J}(\bar{\boldsymbol{\eta}}_2)\dot{\boldsymbol{\eta}}_{Rw}, \end{aligned}$$
$$(7)$$

where $\boldsymbol{\eta}_{Rw} \in \mathbb{R}^6$ is the WF motion vector in the hydrodynamics frame. $\boldsymbol{\eta}_w \in \mathbb{R}^6$ is the WF motion vector in the Earth-fixed frame. $\boldsymbol{\tau}_{\text{wave1}} \in \mathbb{R}^6$ is the first-order wave excitation vector, which will be modified for varying vessel headings relative to the incident wave direction. $\mathbf{M}(\omega) \in \mathbb{R}^{6 \times 6}$ is the system inertia matrix containing frequency dependent added mass coefficients in addition to the vessel's mass and moment of inertia. $\mathbf{D}_p(\omega) \in \mathbb{R}^{6 \times 6}$ is the wave radiation (potential) damping matrix. The linearized restoring coefficient matrix $\mathbf{G} \in \mathbb{R}^{6 \times 6}$ is due to gravity and buoyancy affecting heave, roll, and pitch only. For anchored vessels, it is assumed that the mooring system will not influence the WF motions.

Remark 1 Generally, a time domain equation cannot be expressed with frequency domain coefficient – ω. However, this is a common used formulation denoted as a pseudo-differential equation. An important feature of the added mass terms and the wave radiation damping terms is the memory effects, which in particular are important to consider for nonstationary cases, e.g., rapid changes of heading angle. Memory effects can be taken into account by introducing a convolution integral or a so-called retardation function (Newman 1977) or state space models as suggested by Fossen (2011).

Control Plant Model

For the purpose of controller design and analysis, it is convenient to apply model reduction and derive a LF and WF control plant model in surge, sway, and yaw about zero vessel velocity according to

$$\dot{\mathbf{p}}_w = \mathbf{A}_{pw}\mathbf{p}_w + \mathbf{E}_{pw}\mathbf{w}_{pw}, \quad (8)$$

$$\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi)\boldsymbol{v}, \quad (9)$$

$$\dot{\mathbf{b}} = -\mathbf{T}_b\mathbf{b} + \mathbf{E}_b\mathbf{w}_b, \quad (10)$$

$$\mathbf{M}\dot{\boldsymbol{v}} = -\mathbf{D}_L\boldsymbol{v} + \mathbf{R}^T(\psi)\mathbf{b} + \boldsymbol{\tau}, \quad (11)$$

$$\dot{\omega}_p = 0, \quad (12)$$

$$\mathbf{y} = \left[\left(\boldsymbol{\eta} + \mathbf{C}_{pw}\mathbf{p}_w \right)^T \quad \omega_p \right]^T, \quad (13)$$

where $\omega_p \in \mathbb{R}$ is the peak frequency of the waves (PFW). The estimated PFW can be calculated by spectral analysis of the pitch and roll measurements assumed to dominantly oscillate at the peak wave frequency. In the spectral analysis, the discrete Fourier transforms of the measured roll and pitch, which are collected through a period of time, are done by taking the n-point fast Fourier transform (FFT). The PFW may be found to be the frequency at which the power spectrum is maximal. The assumption $\dot{\omega}_p = 0$ is valid for slowly varying sea state. You can also find the wave frequency using nonlinear observers/EKF and signal processing techniques. It is assumed that the second-order linear model is sufficient to describe the first-order wave-induced motions, and then $\mathbf{p}_w \in \mathbb{R}^6$ is the state of the WF model. $\mathbf{A}_{pw} \in \mathbb{R}^{6 \times 6}$ is assumed Hurwitz and describes the first-order wave-induced motion as a

mass-damper-spring system. $\mathbf{w}_{pw} \in \mathbb{R}^3$ is a zero-mean Gaussian white noise vector. $\mathbf{y}$ is the measurement vector. The WF measurement matrix $\mathbf{C}_{pw} \in \mathbb{R}^{3\times6}$ and the disturbance matrix $\mathbf{E}_{pw} \in \mathbb{R}^{6\times3}$ are formulated as

$$\mathbf{C}_{pw} = \begin{bmatrix} \mathbf{0}_{3\times3} & \mathbf{I}_{3\times3} \end{bmatrix}, \mathbf{E}_{pw}^T = \begin{bmatrix} \mathbf{0}_{3\times3} & \mathbf{K}_w^T \end{bmatrix}^T. \tag{14}$$

Here, a 3-DOF model is assumed adopting the notation in (3) such that $\boldsymbol{\eta} \in \mathbb{R}^3$ and $\boldsymbol{\upsilon} \in \mathbb{R}^3$ are the LF position vector in the Earth-fixed frame and the LF velocity vector in the body-fixed frame, respectively. $\mathbf{M} \in \mathbb{R}^{3\times3}$ and $\mathbf{D}_L \in \mathbb{R}^{3\times3}$ are the mass matrix including hydrodynamic added mass and linear damping matrix, respectively. The bias term accounting for unmodeled affects and slowly varying disturbances $\mathbf{b} \in \mathbb{R}^3$ is modeled as Markov processes with positive definite diagonal matrix $\mathbf{T}_b \in \mathbb{R}^{3\times3}$ of time constants. If $\mathbf{T}_b$ is removed, a Wiener process is used. $\mathbf{w}_b \in \mathbb{R}^3$ is a bounded disturbance vector, and $\mathbf{E}_b \in \mathbb{R}^{3\times3}$ is a disturbance scaling matrix. $\boldsymbol{\tau} \in \mathbb{R}^3$ is the control force. As mentioned later in the paper, the proposed model reduction considering only horizontal motions may create problems conducting DP operations of structures with low waterplane area such as semisubmersibles. More details can be found in Sørensen (2011) and Fossen (2011) and the references therein.

For underwater vehicles, 6-DOF model should be used. For underwater vehicles with self-stabilizing roll and pitch, a 4-DOF model with surge, sway, yaw, and heave may be used; see Sørensen et al. (2012).

Control Levels and Integration Aspects

The real-time control hierarchy of a marine control system (Sørensen 2005) may be divided into three levels: *the guidance system and local optimization*, *the high-level plant control* (e.g., DP controller including thrust allocation), and *the low-level thruster control*. The DP control system consists of several modules as indicated in Fig. 1:

- *Signal processing* for analysis and testing of the individual signals including voting and weighting when redundant measurements are available. Ensuring robust and fault-tolerant control proper diagnostics and change detection algorithms is regarded as maybe one of the most important research areas. For an overview of the field, see Basseville and Nikiforov (1993) and Blanke et al. (2003).

- *Vessel observer* for state estimation and wave filtering. In case of lost sensor signals, the predictor is used to provide dead reckoning, which is required by class societies. Prediction error which is the deviation between the measurements and the estimated measurements is also one important barrier in the failure detection.

- *Feedback control law* is often of multivariable PID type, where feedback is produced from the estimated low-frequency (LF) position and heading deviations and estimated LF velocities.

- *Feedforward control law* is normally the wind force and moment. For the different applications (pipe laying, ice operations, position mooring), tailor-made feedforward control functions are also used.

- *Guidance system with reference models* is needed in achieving a smooth transition between setpoints. In the most basic case, the operator specifies a new desired position and heading, and a reference model generates smooth reference trajectories/paths for the vessel to follow. A more advanced guidance system involves way-point tracking functionality with optimal path planning.

- *Thrust allocation* computes the force and direction commands to each thruster device based on input from the resulting feedback and feedforward controllers. The low-level thruster controllers will then control the propeller pitch, speed, torque, and power.

- *Model adaptation* provides the necessary corrections of the vessel model and the controller settings subject to changes in the vessel draft, wind area, and variations in the sea state.

- *Power management system* performs diesel engine control, power generation management with frequency and voltage monitoring, active and passive load sharing, and load dependent start and stop of generator sets.

DP Controller

In the 1960s the first DP system was introduced for horizontal modes of motion (surge, sway, and yaw) using single-input single-output PID control algorithms in combination with low-pass and/or notch filters. In the 1970s more advanced output control methods based on multivariable optimal control and Kalman filter theory were proposed by Balchen et al. (1976) and later refined in Sælid et al. (1983); Grimble and Johnson (1988); and others as referred to in Sørensen (2011). In the 1990s nonlinear DP controller designs were proposed by several research groups; for an overview see Strand et al. (1998), Fossen and Strand (1999), Pettersen and Fossen (2000), and Sørensen (2011). Nguyen et al. (2007) proposed the design of hybrid controller for DP from calm to extreme sea conditions.

Plant Control

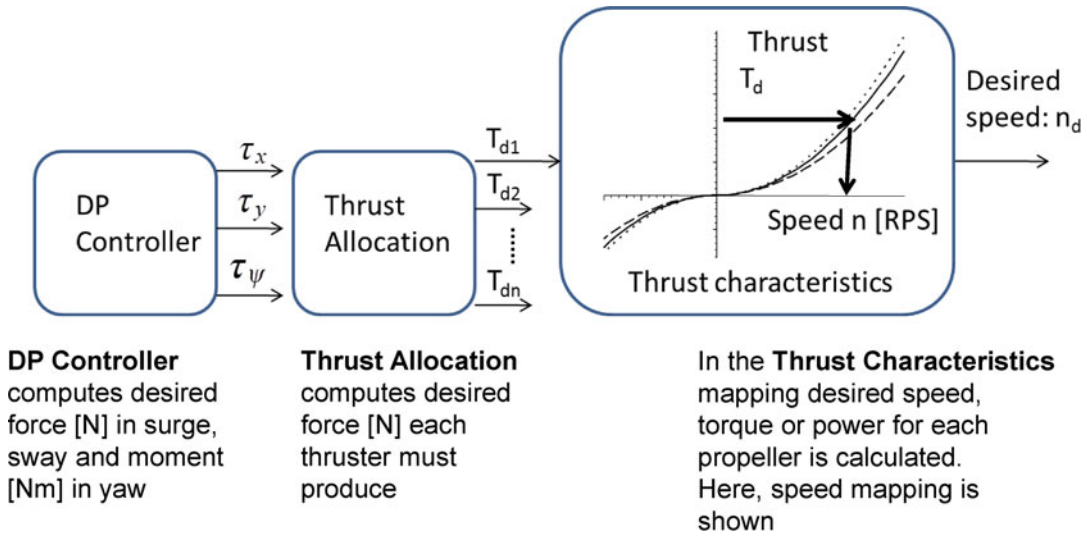
By copying the control plant model (8)–(13) and adding an injection term, a passive observer may

be designed. A nonlinear output horizontal-plane positioning feedback controller of PID type may be formulated as

$$\boldsymbol{\tau}_{PID} = -\mathbf{R}_e^{\mathbf{T}}\mathbf{K_p}\mathbf{e} - \mathbf{R}_e^{\mathbf{T}}\mathbf{K_{p3}}\mathbf{f(e)} - \mathbf{K_d}\tilde{\boldsymbol{v}} - \mathbf{R}^{\mathbf{T}}\mathbf{K_i}\mathbf{z}, \tag{15}$$

where $\mathbf{e} \in \mathbb{R}^3$ is the position and heading deviation vector, $\tilde{\boldsymbol{v}} \in \mathbb{R}^3$ is the velocity deviation vector, $\mathbf{z} \in \mathbb{R}^3$ is the integrator states, and $\mathbf{f(e)}$ is a third-order stiffness term defined as

$$\begin{aligned}
\mathbf{e} &= [e_1, e_2, e_3]^T = \mathbf{R}^T(\phi_d)(\widehat{\boldsymbol{\eta}} - \boldsymbol{\eta}_d), \\
\tilde{\boldsymbol{v}} &= \widehat{\boldsymbol{v}} - \mathbf{R}^T(\phi_d)\boldsymbol{\eta}_d, \\
\dot{\mathbf{z}} &= \widehat{\boldsymbol{\eta}} - \boldsymbol{\eta}_d, \\
\mathbf{R}_e &= \mathbf{R}(\phi - \phi_d) = \mathbf{R}^T(\phi_d)\mathbf{R}(\phi), \\
\mathbf{f(e)} &= [e_1^3, e_2^3, e_3^3]^T.
\end{aligned}$$

Experience from implementation and operations of real DP control systems has shown that ϕ_d in the calculation of the error vector $\mathbf{e}$ generally gives a better performance with less noisy signals than using ϕ. However, this is only valid


Dynamic Positioning Control Systems for Ships and Underwater Vehicles, Fig. 2 Thrust allocation

under the assumption that the vessel maintains its desired heading with small deviations. As the DP capability for ships is sensitive to the heading angle, i.e., minimizing the environmental loads, heading control is prioritized in case of limitations in the thrust capacity. This feature is handled in the thrust allocation.

An advantage of this is the possibility to reduce the first-order proportional gain matrix, resulting in reduced dynamic thruster action for smaller position and heading deviations. Moreover, the third-order restoring term will make the thrusters to work more aggressive for larger deviations. $\mathbf{K}_p$, $\mathbf{K}_{p3}$, $\mathbf{K}_d$, and $\mathbf{K}_i \in \mathbb{R}^{3 \times 3}$ are the nonnegative controller gain matrices for proportional, third-order restoring, derivative, and integrator controller terms, respectively, found by appropriate controller synthesis methods.

For small-waterplane-area marine vessels such as semisubmersibles, often used as drilling rigs, Sørensen and Strand (2000) proposed a DP control law with the inclusion of roll and pitch damping according to

$$\tau_{rpd} = - \begin{bmatrix} 0 & g_{xq} \\ g_{yp} & 0 \\ g_{\phi p} & 0 \end{bmatrix} \begin{bmatrix} \widehat{p} \\ \widehat{q} \end{bmatrix}, \qquad (16)$$

where $\widehat{p}$ and $\hat{q}$ are the estimated pitch and roll angular velocities. The resulting positioning control law is written as

$$\tau = \tau_{wFF} + \tau_{PID} + \tau_{rpd}, \qquad (17)$$

where $\tau_{wFF} \in \mathbb{R}^3$ is the wind feedforward control law.

Thrust allocation or control allocation (Fig. 2) is the mapping between plant and actuator control. It is assumed to be a part of the plant control. The DP controller calculated the desired force in surge and sway and moment in yaw. Dependent on the particular thrust configuration with installed and enabled propellers, tunnel thrusters, azimuthing thrusters, and rudders, the allocation is a nontrivial optimization problem calculating the desired thrust and direction for each enabled thruster subject to various constraints such as thruster ratings, forbidden sectors, and thrust efficiency. References on thrust allocation are found in Johansen and Fossen (2013).

In Sørensen and Smogeli (2009), torque and power control of electrically driven marine propellers are shown. Ruth et al. (2009) proposed anti-spin thrust allocation, and Smogeli et al.

(2008) and Smogeli and Sørensen (2009) presented the concept of anti-spin thruster control.

University of Florence, Italy

Abstract

Economic model predictive control (EMPC) is a variant of model predictive control aimed at maximization of system's profitability. It allows one to explicitly deal with hard and average constraints on system's input and output variables as well as with nonlinearity of dynamics. We provide basic definitions and concepts of the approach and highlight some promising research directions.

Keywords

Constrained systems; Dynamic programming; Profit maximization

Introduction

Most control tasks involve some kind of economic optimization. In classical linear quadratic (LQ) control, for example, this is cast as a trade-off between control effort and tracking performance. The designer is allowed to settle such a trade-off by suitably tuning weighting parameters of an otherwise automatic design procedure.

When the primary goal of a control system is profitability rather than tracking performance, a suboptimal approach has often been devised, namely, a hierarchical separation is enforced between the economic optimization layer and the dynamic real-time control layer.

In practice, while set points are computed by optimizing economic revenue among all equilibria fulfilling the prescribed constraints, the task of the real-time control layer is simply to drive (basically as fast as possible) the system's state to the desired set-point value.

Optimal control or LQ control may be used to achieve the latter task, possibly in conjunction with model predictive control (MPC), but the actual economics of the plant are normally neglected at this stage.

The main benefits of this approach are twofold:

1. Reduced computational complexity with respect to infinite-horizon dynamical programming
2. Stability robustness in the face of uncertainty, normally achieved by using some form of robust control in the real-time control layer

The hierarchical approach, however, is suboptimal in two respects:

1. First of all, given nonlinearity of the plant's dynamics and/or nonconvexity of the

functions characterizing the economic revenue, there is no reason why the most profitable regime should be an equilibrium.

2. Even when systems are most profitably operated at equilibrium, transient costs are totally disregarded by the hierarchical approach and this may be undesirable if the time constants of the plant are close enough to the time scales at which set point's variations occur.

Economic model predictive control seeks to remove these limitations by directly using the economic revenue in the stage cost and by the formulation of an associated dynamic optimization problem to be solved online in a receding horizon manner. It was originally developed by Rawlings and co-workers, in the context of linear control systems subject to convex constraints as an effective technique to deal with infeasible set points (Rawlings et al. 2008) (in contrast to the classical approach of redesigning a suitable quadratic cost that achieves its minimum at the closest feasible equilibrium). Preserving the original cost has the advantage of slowing down convergence to such an equilibrium when the transient evolution occurs in a region where the stage cost is better than at steady state. Stability and convergence issues are at first analyzed, thanks to convexity and for the special case of linear systems only. Subsequently Diehl introduced the notion of rotated cost (see Diehl et al. 2011) that allowed a Lyapunov interpretation of stability criteria and paved the way for the extension to general dissipative nonlinear systems (Angeli et al. 2012).

Economic MPC Formulation

In order to describe the most common versions of economic MPC, assume that a discrete-time finite-dimensional model of state evolution is available for the system to be controlled:

$$x^+ = f(x, u) \qquad (1)$$

where $x \in X \subset \mathbb{R}^n$ is the state variable, $u \in U \subset \mathbb{R}^m$ is the control input, and $f : X \times U \to X$ is a continuous map which computes the next state value, given the current one and the value of

the input. We also assume that $\mathbb{Z} \subset X \times U$ is a compact set which defines the (possibly coupled) state/input constraints that need to hold pointwise in time:

$$(x(t), u(t)) \in \mathbb{Z} \qquad \forall t \in \mathbb{N}. \qquad (2)$$

In order to introduce a measure of economic performance, to each feasible state/input pair $(x, u) \in \mathbb{Z}$, we associate the instantaneous net cost of operating the plant at that state when feeding the specified control input:

$$\ell(x, u) \; : \; \mathbb{Z} \to \mathbb{R}. \qquad (3)$$

The function ℓ (which we assume to be continuous) is normally referred to as stage cost and together with actuation and/or inflow costs should also take into account the profits associated to possible output/outflows of the system. Let (x^*, u^*) denote the best equilibrium/control input pair associated to (3) and (2), namely,

$$\begin{aligned} \ell(x^*, u^*) = \min_{x,u} \ell(x, u) \\ \text{subject to} \\ (x, u) \in \mathbb{Z} \\ x = f(x, u) \end{aligned} \qquad (4)$$

Notice that, unlike in tracking MPC, it is not assumed here that

$$\ell(x^*, u^*) \le \ell(x, u) \quad \forall(x, u) \in \mathbb{Z}. \qquad (5)$$

This is, technically speaking, the main point of departure between economic MPC and tracking MPC.

As there is no natural termination time to operation of a system, our goal would be to optimize the infinite-horizon cost functional:

$$\sum_{t \in \mathbb{N}} \ell(x(t), u(t)) \qquad (6)$$

possibly in an average sense (or by introducing some discounting factor to avoid infinite costs) and subject to the dynamic/operational constraints (1) and (2).

To make the problem computationally more tractable and yet retain some of the desirable economic benefits of dynamic programming, (6) is truncated to the following cost functional:

$$J(\mathbf{z}, \mathbf{v}) = \sum_{k=0}^{N-1} \ell(z(k), v(k)) + V_f(z(N)) \quad (7)$$

where $\mathbf{z} = [z(0), z(1), \ldots, z(N)] \in X^{N+1}, \mathbf{v} = [v(0), v(1), \ldots, v(N-1)] \in U^N$ and $V_f \colon X \to \mathbb{R}$ is a terminal weighting function whose properties will be specified later.

The virtual state/control pair $(\mathbf{z}^*, \mathbf{v}^*)$ at time t is the solution (which for the sake of simplicity we assume to be unique) of the following optimization problem:

$$\begin{aligned} V(x(t)) &= \min_{\mathbf{z}, \mathbf{v}} J(\mathbf{z}, \mathbf{v}) \\ &\text{subject to} \\ &z(k+1) = f(z(k), v(k)) \\ &(z(k), v(k)) \in \mathbb{Z} \\ &\text{for } k \in \{0, 1, \ldots, N-1\} \\ &z(0) = x(t), \ z(N) \in \mathbb{X}_f. \end{aligned} \quad (8)$$

Notice that $z(0)$ is initialized at the value of the current state $x(t)$. Thanks to this fact, $\mathbf{z}^*$ and $\mathbf{v}^*$ may be seen as functions of the current state $x(t)$. At the same time, $z(N)$ is constrained to belong to the compact set $\mathbb{X}_f \subset X$ whose properties will be detailed in the next paragraph.

As customary in model predictive control, a state-feedback law is defined by applying the first virtual control to the plant, that is, by letting $u(t) = v^*(0)$ and restating, at the subsequent time instant, the same optimization problem from initial state $x(t+1)$ which, in the case of exact match between plant and model, can be computed as $f(x(t), u(t))$.

In the next paragraph, we provide details on how to design the "terminal ingredients" (namely, V_f and $\mathbb{X}_f$) in order to endow the basic algorithm (8) with important features such as recursive feasibility and a certain degree of average performance and/or stability).

Hereby it is worth pointing out how, in the context of economic MPC, it makes sense to treat, together with pointwise-in-time constraints, asymptotic average constraints on specified input/output variables. In tracking applications, where the control algorithm guarantees asymptotic convergence of the state to a feasible set point, the average asymptotic value of all input/output variables necessarily matches that of the corresponding equilibrium/control input pair. In economic MPC, the asymptotic regime resulting in closed loop may, in general, fail to be an equilibrium; therefore, it might be of interest to impose average constraints on system's inflows and outflows which are more stringent than those indirectly implied by the fulfillment of (2). To this end, let the system's output be defined as

$$y(t) = h(x(t), u(t)) \quad (9)$$

with $h(x, u) : \mathbb{Z} \to \mathbb{R}^p$, a continuous map, and consider the convex compact set $\mathbb{Y}$. We may define the set of asymptotic averages of a bounded signal y as follows:

$$\mathrm{Av}[y] = \left\{ \eta \in \mathbb{R}^p : \exists \{t_n\}_{n=1}^{\infty} : t_n \to \infty \text{ as } n \to \infty \right.$$
$$\left. \text{and } \eta = \lim_{n \to \infty} \left(\sum_{k=0}^{t_n-1} y(k) \right) / t_n \right\}$$

Notice that for converging signals, or even for periodic ones, $\mathrm{Av}[y]$ always is a singleton but may fail to be such for certain oscillatory regimes. An asymptotic average constraint can be expressed as follows:

$$\mathrm{Av}[y] \subseteq \mathbb{Y} \quad (10)$$

where y is the output signal as defined in (9).

Basic Theory

The main theoretical results in support of the approach discussed in the previous paragraph are discussed below. Three fundamental aspects are treated:

- Recursive feasibility and constraint satisfaction
- Asymptotic performance
- Stability and convergence

Feasibility and Constraints

The departing point of most model predictive control techniques is to ensure recursive feasibility, namely, the fact that feasibility of the problem (8) at time 0 implies feasibility at all subsequent times, provided there is no mismatch between the true plant and its model (1). This is normally achieved by making use of a suitable notion of control invariant set which is used as a terminal constraint in (8). Economic model predictive control is not different in this respect, and either one of the following set of assumptions is sufficient to ensure recursive feasibility:

1. **Assumption 1: Terminal constraint**

$$\mathbb{X}_f = \{x^*\} \qquad V_f = 0$$

2. **Assumption 2: Terminal penalty function**

There exists a continuous map $\kappa : \mathbb{X}_f \to U$ such that

$$(x, \mathbb{K}(x)) \in \mathbb{Z} \qquad \forall x \in \mathbb{X}_f$$
$$f(x, \mathbb{K}(x)) \in \mathbb{X}_f \qquad \forall x \in \mathbb{X}_f$$

The following holds:

Theorem 1 *Let $x(0)$ be a feasible state for (8) and assume that either Assumption 1 or 2 hold. Then, the closed-loop trajectory $x(t)$ resulting from receding horizon implementation of the feedback $u(t) = v^*(0)$ is well defined for all $t \in \mathbb{N}$ (i.e., $x(t)$ is a feasible initial state of (8) for all $t \in \mathbb{N}$) and the resulting closed-loop variables $(x(t), u(t))$ fulfill the constraints in (2).*

The proof of this Theorem can be found in Angeli et al. (2012) and Amrit et al. (2011), for instance. When constraints on asymptotic averages are of interest, the optimization problem (8) can be augmented by the following constraints:

$$\sum_{k=0}^{N-1} h(z(k), v(k)) \in \mathbb{Y}_t \qquad (11)$$

provided $\mathbb{Y}_t$ is recursively defined as

$$\mathbb{Y}_{t+1} = \mathbb{Y}_t \oplus \mathbb{Y} \oplus \{-h(x(t), u(t))\} \qquad (12)$$

where $\oplus$ denotes Pontryagin's set sum. ($A \oplus B := \{c : \exists a \in A, \exists b \in B : c = a + b\}$) The sequence is initialized as $\mathbb{Y}_0 = N\mathbb{Y} \oplus \mathbb{Y}_{00}$ where $\mathbb{Y}_{00}$ is an arbitrary compact set in $\mathbb{R}^p$ containing 0 in its interior. The following result can be proved.

Theorem 2 *Consider the optimization problem (8) with additional constraints (11), and assume that $x(0)$ is a feasible initial state. Then, provided a terminal equality constraint is adopted, the closed-loop solution $x(t)$ is well defined and feasible for all $t \in \mathbb{N}$ and the resulting closed-loop variable $y(t) = h(x(t), u(t))$ fulfills the constraint (10).*

Extending average constraints to the case of economic MPC with terminal penalty function is possible but outside the scope of this brief tutorial. It is worth mentioning that the set $\mathbb{Y}_{00}$ plays the role of an initial allowance that is shrunk or expanded as a result of how close are closed-loop output signals to the prescribed region. In particular, $\mathbb{Y}_{00}$ can be selected a posteriori (after computation of the optimal trajectory) just for $t = 0$, so that the feasibility region of the algorithm is not affected by the introduction of average asymptotic constraints.

Asymptotic Average Performance

Since economic MPC does not necessarily lead to converging solutions, it is important to have bounds which estimate the asymptotic average performance of the closed-loop plant. To this end, the following dissipation inequality is needed for the approach with terminal penalty function:

$$V_f(f(x, \mathbb{K}(x))) \le V_f(x) - \ell(x, \mathbb{K}(x)) + \ell(x^*, u^*) \qquad (13)$$

which shall hold for all $x \in \mathbb{X}_f$. We are now ready to state the main bound on the asymptotic performance:

Theorem 3 *Let $x(0)$ be a feasible state for (8) and assume that either Assumption 1 or Assumption 2 together with (13) hold. Then, the closed-loop trajectory $x(t)$ resulting from receding horizon implementation of the feedback $u(t) = v^*(0)$ is well defined for all $t \in \mathbb{N}$ and fulfills*

$$\limsup_{T \to +\infty} \frac{\sum_{t=0}^{T-1} \ell(x(t), u(t))}{T} \le \ell(x^*, u^*). \quad (14)$$

The proof of this fact can be found in Angeli et al. (2012) and Amrit et al. (2011). When periodic solutions are known to outperform, in an average sense, the best equilibrium/control pair, one may replace terminal equality constraints by periodic terminal constraints (see Angeli et al. 2012). This leads to an asymptotic performance at least as good as that of the solution adopted as a terminal constraint.

Stability and Convergence

It is well known that the cost-to-go $V(x)$ as defined in (8) is a natural candidate Lyapunov function for the case of tracking MPC. In fact, the following estimate holds along solutions of the closed-loop system:

$$V(x(t+1)) \le V(x(t)) - \ell(x(t), u(t)) + \ell(x^*, u^*). \quad (15)$$

This shows, thanks to inequality (5), that $V(x(t))$ is nonincreasing. Owing to this, stability and convergence can be easily achieved under mild additional technical assumptions. While property (15) holds for economic MPC, both in the case of terminal equality constraint and terminal penalty function, it is no longer true that (5) holds. As a matter of fact, x^* might even fail to be an equilibrium of the closed-loop system, and hence, convergence and stability cannot be expected in general.

Intuitively, however, when the most profitable operating regime is an equilibrium, the average performance bound provided by Theorem 3 seems to indicate that some form of stability or convergence to x^* could be expected. This is true under an additional dissipativity assumption which is closely related to the property of optimal operation at steady state.

Definition 1 A system is strictly dissipative with respect to the supply function $s(x, u)$ if there exists a continuous function $\lambda : X \to \mathbb{R}$ and $\rho : X \to \mathbb{R}$ positive definite with respect to x^* such that for all x and u in $X \times U$, it holds:

$$\lambda(f(x, u)) \le \lambda(x) + s(x, u) - \rho(x). \quad (16)$$

The next result highlights the connection between dissipativity of the open-loop system and stability of closed-loop economic MPC.

Theorem 4 *Assume that either Assumption 1 or Assumption 2 together with (13) hold. Let the system (1) be strictly dissipative with respect to the supply function $s(x, u) = \ell(x, u) - \ell(x^*, u^*)$ as from Definition 1 and assume there exists a neighborhood of feasible initial states containing x^* in its interior. Then provided V is continuous at x^*, x^* is an asymptotically stable equilibrium with basin of attraction equal to the set of feasible initial states.*

See Angeli et al. (2012) and Amrit et al. (2011) for proofs and discussions. Convergence results are also possible for the case of economic MPC subject to average constraints. Details can be found in Müller et al. (2013a).

Hereby it is worth mentioning that finding a function satisfying (16) (should one exist) is in general a hard task (especially for nonlinear systems and/or nonconvex stage costs); it is akin to the problem of finding a Lyapunov function and therefore general construction methods do not exist. Let us emphasize, however, that while existence of a storage function λ is a sufficient condition to ensure convergence of closed-loop economic MPC, formulation and resolution of the optimization problem (8) can be performed irrespectively of any explicit knowledge of such function. Also, we point out that existence of λ as in Definition 1 and Theorem 4 is only possible if the optimal infinite-horizon regime of operation for the system is an equilibrium.

Summary and Future Directions

Economic model predictive control is a fairly recent and active area of research with great potential in those engineering applications where economic profitability is crucial rather than tracking performance.

The technical literature is rapidly growing in application areas such as chemical engineering

(see Heidarinejad 2012) or power systems engineering (see Hovgaard et al. 2010; Müller et al. 2013a) where system's output is in fact physical outflows which can be stored with relative ease.

We only dealt with the basic theoretical developments and would like to provide pointers to interesting recent and forthcoming developments in this field:

- Generalized terminal constraints: possibility of enlarging the set of feasible initial states by using arbitrary equilibria as terminal constraints, possibly to be updated on line in order to improve asymptotic performance (see Fagiano and Teel 2012; Müller et al. 2013b).
- Economic MPC without terminal constraints: removing the need for terminal constraints by taking a sufficiently long control horizon is an interesting possibility offered by standard tracking MPC. This is also possible for economic MPC at least under suitable technical assumptions as investigated in Grüne (2012, 2013).
- The basic developments presented in the previous paragraph only deal with systems unaffected by uncertainty. This is a severe limitation of current approaches and it is to be expected that, as for the case of tracking MPC, a great deal of research in this area could be developed in the future. In particular, both deterministic and stochastic uncertainties are of interest.

Electric Energy Transfer and Control via Power Electronics

Fred Wang
University of Tennessee, Knoxville, TN, USA

Abstract

Power electronics and their applications for electric energy transfer and control are introduced. The fundamentals of the power electronics are presented, including the commonly used semiconductor devices and power converter circuits. Different types of power electronic controllers for electric power generation, transmission and distribution, and consumption are described. The advantages of power electronics over traditional electromechanical or electromagnetic controllers are explained. The future directions for power electronic application in electric power systems are discussed.

Keywords

Electric energy control; Electric energy transfer; Power electronics

Introduction

Modern society runs on electricity or electric energy. The electric energy generally must be transferred before consumption since the energy sources, such as thermal power plants, hydro dams, and wind farms, are often some distances away from the loads. In addition, electric energy needs to be controlled as well since the energy transfer and use often require electricity in a form different from the raw form generated at the source. Examples are the voltage magnitude and frequency for long distance transmission; the voltage needs to be stepped up at the sending end to reduce the energy loss along the lines and then stepped down at the receiving end for users; for many modern consumer devices, DC voltage is needed and obtained through transforming the 50 or 60 Hz utility power. Note that electric energy transfer and control is often used interchangeably with the electric power transfer and control. This is because the modern electric power systems have very limited energy storage and the energy generated must be consumed at the same time.

Since the beginning of the electricity era, electric energy transfer and control technologies have been an essential part of electric power systems. Many types of equipment were invented and applied for these purposes. The commonly used equipment includes electric transmission and distribution lines, generators, transformers, switchgears, inductors or reactors, and capacitor banks. The traditional equipment has limited control capability. Many cannot be controlled at all or can only be connected or disconnected with mechanical switches, others with limited range, such as transformers with tap changers. Even with fully controllable equipment such as generators, the control dynamics is relatively slow due to the electromechanical or magnetic nature of the controller.

Power electronics are based on semiconductor devices. These devices are derivatives from transistors and diodes used in microelectronic circuits with the additional large power handling capability. Due to their electronic nature, power electronic devices are much more flexible and faster than their electromechanical or electromagnetic

counterparts for electric energy transfer and control. Since the advent of power electronics in the 1950s, they have steadily gained ground in power system applications. Today, power electronic controllers are an important part of equipment for electric energy transfer and control. Their roles are growing rapidly with the continuous improvement of the power electronic technologies.
Fundamentals of Power Electronics

Different from semiconductor devices in microelectronics, the power electronic devices only act as switches for desired control functions, such that they incur minimum losses when they are either on (closed) or off (open). As a result, the power electronic controllers are basically the switching circuits. The semiconductor switches are therefore the most important elements of the power electronic controllers. Since the 1950s, many different types of power semiconductor switches have been developed and can be selected based on the applications.

The performance of the power semiconductor devices is mainly characterized by their voltage and current ratings, conduction or on-state loss, as well as the switching speed (or switching frequency capability) and associated switching loss. Main types of power semiconductor devices are listed with their symbols and state-of-the-art rating and frequency range shown in Table 1:

- Power diode – a two terminal device with similar characteristics to diodes used in microelectronics but with higher-voltage and power ratings.

- Thyristor – also called SCR (silicon-controlled rectifier). Unlike diode, thyristor is a three-terminal device with an additional gate terminal. It can be turned on by a current pulse through gate but can only be turned off when the main current goes to zero with external means. Thyristor has low conduction loss but slow switching speed.
- GTO – stands for gate-turn-off thyristor. GTO can be turned on similarly as a regular thyristor and can also be turned off with a large negative gate current pulse. GTO has been largely replaced by IGBT and IGCT due to its complex gate driving needs and slow switching speed.
- Power BJT – similar to bipolar transistor for microelectronics and requires a sustained gate current to turn on and off. It has been replaced by IGBT and power MOSFET with simpler gate signals and faster switching speed.
- Power MOSFET – similar to metal-oxide semiconductor field effect transistor for microelectronics and can be turned on and off with a gate voltage signal. It is the fastest device available but has relatively high conduction loss and relatively low-voltage/power ratings.
- IGBT – stands for insulated-gate bipolar transistor. Unlike regular BJT, it can be turned on and off with a gate voltage like MOSFET. It has relatively low conduction loss and fast switching speed. IGBT is becoming the workhorse of the power electronics for high power applications.

Electric Energy Transfer and Control via Power Electronics, Table 1 Commonly use Si-based power semiconductor devices and their ratings

Types	Symbol	Voltage	Current	Switching frequency
Power diodes		Max 80 kV, typical < 10 kV	10 kA	Various
Thyristor		Max 8 kV	4.5 kA	AC line frequency
GTO		Max 10 kV	6.5 kA	<500 Hz
Power MOSFET		Max 4.5 kV, typical < 600 V	1.6 kA	10 s of kHz to MHz
IGBT		Max 6.5 kV, typical > 600 V	2.4 kA	1 kHz to 10 s of kHz
IGCT		Max 10 kV, typical > 4.5 kV	6.5 kA	<2 kHz

- IGCT – stands for integrated-gate-commutated thyristor. It is basically a GTO with an integrated gate drive circuit allowing a hard driven turnoff. It therefore has faster switching speed than regular GTO but slower than IGBT.

Except for diodes, all other devices above can be turned on and/or off through a gate signal, so they are active switches, while diodes are called passive switch.

With different types of power semiconductors, many power electronics circuits have been developed. Based on their functions, they can be classified as:

- Rectifier – rectifiers convert AC to DC. Depending on AC sources, rectifiers can be three phase or single phase; depending on device types, they can be passive (diode based), phase controlled (thyristor controlled), or actively switched.
- Inverter – inverters convert DC to AC. They again can be three phase or single phase. Inverters generally require active switching devices.
- DC-DC converter – also called choppers, DC-DC converters convert one DC voltage level to another. Sometimes they also contains a magnetic isolation. DC-DC converters can have unidirectional or bidirectional power flow and generally requires active switching devices.
- AC-AC converter – directly converts one AC to another, either only the voltage magnitude or both magnitude and frequency. The former can also be called AC switch, and the latter can

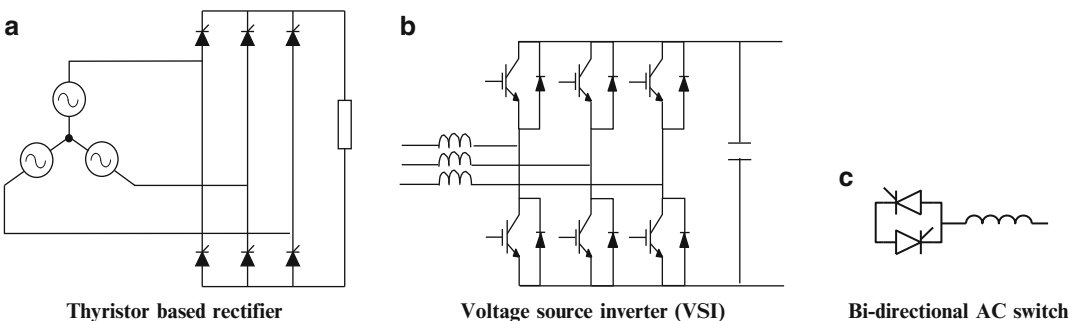
be called frequency changer. Active devices are needed for these types of converters.

There are a variety of converter topologies for each type of the converters listed above. The most commonly used basic topologies for power system applications are shown in Fig. 1. These basic topologies can be expanded through paralleling or series of devices and/or converters to achieve higher current and voltage ratings. Other variations such as multilevel converters are also popular for high-voltage applications using lower-voltage rating devices.

It should be noted that passive components, i.e., inductors and capacitors, are essential parts of power electronic converters. In fact, power electronic converters transfer or control the electric energy by storing it temporarily in inductors or capacitors while reformatting the original voltage or current waveform through switching actions. The other key function of the passives is filtering the harmonics caused by switching.

Power Electronic Controller Types for Energy Transfer and Control

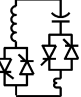
For almost all traditional non-power-electronic equipment for electric energy transfer and control, there can be corresponding power electronic-based counterpart, often with better controllability. However, power electronic equipment can be more expensive and therefore only used when it provides better overall performance and cost benefits. In other cases, only power electronic equipment can achieve the required control functions.

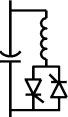
a Thyristor based rectifier   **b** Voltage source inverter (VSI)   **c** Bi-directional AC switch


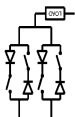
Electric Energy Transfer and Control via Power Electronics, Fig. 1 Commonly used basic power electronics converter topologies (only one phase shown for the AC switch)

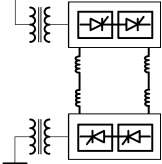
The power electronic controllers can be categorized as for energy generation, delivery, and consumption. For generation, the thermal or hydro generators both use synchronous machines with excitation windings on the rotor, which require DC current. A thyristor-based rectifier, called exciter, is generally used for this purpose. Wind turbine generators usually use a back-to-back VSI to interface to the AC grid, and PV solar sources use a DC-DC converter cascaded with a VSI.

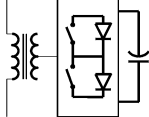
Power electronic controllers for transmission and distribution controllers include so-called flexible AC transmission systems (FACTS) and high-voltage DC transmission (HVDC). Some of the more commonly used controllers and their functions and circuit topologies are listed in Table 2.

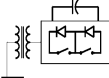
The main power electronic controllers for loads include variable speed motor drives; electronic ballast for fluorescent lights and power supplies for LED; various power supplies for computer, IT, and other electronic loads; and chargers for electric vehicles. The percentage of power electronics controlled loads in power systems have been steadily increasing. Power electronics can generally result in improved performance and efficiency.


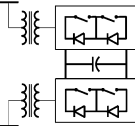












Future Directions

Power electronics have progressed steadily since the invention of thyristors in the 1950s. The progress is in all aspects, semiconductor devices, passives, circuits, control, and system integration, leading to converter systems with better performance, higher efficiency, higher power density, higher reliability, and lower cost. Because of these progresses, the power electronics applications in power systems have become more and more widespread. However, in general, power electronic controllers are still not sufficiently cost-effective, reliable, or efficient. Many improvements are needed and expected, especially in the following areas:

- Semiconductor devices – Devices used today are almost exclusively based on silicon. The emerging devices based on wide-bandgap materials such as SiC and GaN are expected to revolutionize power electronics with their capabilities of higher voltage, lower loss, faster switching speed, higher temperature, and smaller size.
- Power electronic converters – More cost-effective and reliable converters will be developed as a result of better devices, passive components, and circuit structures. Modular, distributed, and hybrid with non-power-electronics approaches are expected to result in overall better benefits.
- Enhanced functions – Power electronic controllers can be designed to have multiple functions in the system. For example, wind and PV solar inverters can provide reactive power to the grid in addition to transferring real energy. Today, power electronic controllers are mostly locally controlled. With better measurement and communication technologies, they may be controlled over a wide area for supporting the system level functions.
- New applications – The new applications for future power system include DC grid based on multiterminal HVDC and energy storage. Critical technologies include cost-effective and efficient DC transformers and DC circuit breakers. Power electronics will play key roles in these technologies.

Engine Control

Luigi del Re
Johannes Kepler Universität, Linz, Austria

Abstract

Engine control is the enabling technology for efficiency, performance, reliability, and cleanliness of modern vehicles for a wide variety of uses and users. It has also a paramount importance for many other engine applications like power plants. Engines are essentially chemical reactors, and the core task of engine control consists in preparing and starting the reaction (mixing the reactants and igniting the mixture) while the reaction itself is not controlled. The technical challenge derives from the combination of high complexity, wide range of conditions of use, performance requirements, significant time delays, and use of the constraints on the choice of components. In practice, engine control is to a large extent feed-forward control, feedback loops being used either for low-level control or for updating the feed-forward. Industrial engine control is based on very complex structures calibrated experimentally, but there is a growing interest for model-based control with stronger feedback action, supported by the breakthrough of new computational and communication possibilities, as well as the introduction of new sensors.

Introduction

Most vehicles are moved by internal combustion engines (ICE), whose key function is the conversion of chemical into mechanical energy, basically by oxidation, e.g., in the case of propane

$$C_3H_8 + 5O_2 = 3CO_2 + 4H_2O + 46.3 \text{ MJ/kg} \quad (1)$$
The chemical energy is first transformed into heat and then converted by the ICE into mechanical energy (Heywood 1988). The key task of engine control (Guzzella and Onder 2010; Kiencke and Nielssen 2005) is to make sure that the reactants (fuel and oxygen) meet in the right proportion ("mixture formation") and that the combustion is started (or "ignited") to deliver the required torque at the engine crankshaft. Several combustion processes are known, the most common ones being Otto and Diesel. For the first kind (also called SI for spark ignited), the mixture is prepared outside the combustion chamber and combustion is ignited by spark, while in the second one fuel is injected directly into the combustion chamber and combustion is ignited by compression (CI, compression ignited). GDI (gasoline direct injection) is a variant of SI engines with direct fuel injection as CI but spark ignition as SI.

Unfortunately, the chemical equation (1) is not the whole truth. Indeed, the way the mixture is prepared and ignited affects the efficiency of the conversion from thermal into mechanical energy, but also secondary reactions, like pollutant formation, and other aspects, like noise, vibrations and harshness (NVH), and mechanical fatigue and thus life expectancy. Furthermore, driveability requirements are primarily determined by the ability of an ICE to change fast its operating point, and this sets additional requirements to the engine control. These requirements have to

be met for all vehicles ín spite of production variability and under all relevant operating conditions, including all drivers, road, traffic, and weather conditions.

As first principle models are often not available or very time-consuming to tune and seldom precise enough, engine control is based on very complex heuristic descriptions which can be tuned experimentally and even automatically (Schoggl et al. 2002) – a modern engine control unit (ECU) can include up to 40.000 labels (parameters or maps). This structure is mainly feedforward, with feedback loops typically used for control of actuators, primarily calibrated under laboratory conditions but with adaptation loops designed to correct parameters to take in account production and wear effects. Figure 1 shows an engine test bench setup with the engine control unit (ECU) and a calibration system.

The Target System

Figure 2 shows the basic setup of an ICE as CI and SI. In both cases, the main components of an ICE are fuel path, air path, combustion chamber, and exhaust aftertreatment system.

Roughly speaking, ICEs exhibit three time scales. Changes in the setting of the fuel path – responsible to deliver the fuel to the combustion chamber – act very fast for CI and GDI engines (e.g., 50 Hz) and rather fast for SI engines (10 Hz or more). The same is not true for the air path which brings the gas mixture (fresh air and possibly recirculated exhaust gas) into the combustion chamber and is the slowest system (typically in the range of 0.5–2 Hz). In SI and GDI engines, spark timing can be changed for each combustion too. A still faster dynamics is associated with the combustion process itself, pressure sensors with the required dynamics to monitor it are being introduced in a growing number of applications, but until now no suitable actuators are available for its closed loop control. The torque demand changes typically with the vehicle dynamics, which are usually still slower than the air path.

The Control Tasks

The high-level control task can be defined as the minimization of the average fuel consumption while providing the required torque and respecting the constraints on emissions (i.e., nitrogen oxides and dioxides (NO_x) and particulate matter (PM)), noise, temperature, etc. The legislators in different countries have defined test procedure, including a specified road profile and corresponding emission limits. Figure 3 shows the progressive reduction of the limits and the speed profile used to assess this value.

Even if fuel consumption is not yet limited by law, the control problem associated can be stated as an optimal constrained control problem:

$$\min_{u(t)} \int_0^{1120} \dot{q}_f \, dt \qquad (2)$$

so that

$$v(t) = v_{\text{dem}}(t) \pm \Delta v \qquad (3)$$

and

$$\int_0^{1120} \dot{q}_i \, dt \leq Q_i \qquad (4)$$

where $u(t)$ are all available control inputs, 1120 is the duration of the European cycle, $v_{\text{dem}}(t)$ the corresponding speed, Δv the speed tolerance, $\dot{q}_f$ is the instantaneous fuel consumption, $\dot{q}_i$ each limited quantity (e.g., NOx), and Q_i the corresponding limit for the whole test. In practice, other criteria must be considered as well, like NVH, but even this problem is never solved using the standard tools of optimal control essentially for the nonlinearity (and following nonconvexity) of the problem, but even more for the lack of explicit models of sufficient quality relating the inputs to the target quantities, especially combustion depending quantities like emissions.

In practice, different simpler subproblems are solved separately and tuned to achieve sufficient results also in terms of the general problem to achieve the required performance. In the following, we concentrate on the main high-level tasks, omitting many others, e.g., all the control loops required for the correct operation of the single actuators.

Air Path Control

The main source of oxygen for the reaction of Eq. (1) is ambient air which contains about 21 % oxygen. The engine – essentially a volumetric air pump – aspires air flow roughly proportional to the cylinder volume and the revolution speed of the engine. The amount of oxygen entering the combustion chamber, however, will depend also on temperature, pressure, and moisture. This flow can be reduced (as in the standard SI engines) by throttling, e.g., by adding an additional flow resistance between the air intake and the combustion chamber, or increased by compressing the fresh air, most commonly by turbocharging (especially in CI engines). A turbocharger consists essentially of a turbine, which transforms part of the enthalpy of the exhaust gas into mechanical power, and a compressor, driven by this power to compress the fresh air on its way to the combustion chamber, thus increasing both its density and temperature. Turbocharger operation is typically controlled either directly (for instance, with variable vane angles) or indirectly, by bypass valves which deviate the gas flows in parallel to the turbine.

If only ambient air is fed to the combustion chamber, a proportional amount of the other gases present in the atmosphere will enter the combustion chamber and be available for combustion side reactions as well. In the case of nitrogen, these reactions lead to the undesired formation of nitrogen oxides (NOx). Therefore, in some engines, especially in CI engines, part of the combusted gases are recirculated to the combustion chamber ("exhaust gas recirculation", EGR), providing advantages in terms of NOx reduction. While EGR is typically realized at high pressures (path HP in Fig. 1), it is realized also at low pressure (path LP), even though less frequently. Typically, the air path includes some coolers designed to increase gas densities.

Air path control is designed to track dynamical references, for instance, the total fresh air mass (MAF) entering the cylinder and the corresponding pressure (MAP), but also other quantities are possible. The references are typically generated by the calibration engineers on the basis of tests. The control inputs of the air path are mostly the turbine (and possibly compressor) steering angle, the EGR, and – if available – throttle(s) setpoints. Most commonly used sensors include a mass flow meter (hot film sensor), rather slow and dynamically not reliable, pressure, and temperature sensors, and sometimes the actual position of the valves is measured as well and the turbocharger speed.

Engine Control, Fig. 4
Pressure trace in a fired
cylinder of a CI engine
triggered by a pilot and a
main injection
Fuel Path Control

The fuel path delivers the correct amount of fuel for the reaction (1). In almost every ICE, a rail is filled with fuel at a given pressure (from few bars for SI to about 2000 bars for CI), from which the required amount of fuel is injected into the cylinder. The injection can occur inside the combustion chamber (as for CI and GDI engines) or near to the intake valve ("port injection") for standard SI engines.

The injection amount is always set taking in account the available oxygen mass. In SI engines with three-way catalyst, the fuel injection is given by the stoichiometric condition. λ control uses an oxygen sensor in the exhaust to determine the actual fuel/oxygen ratio and if appropriate correct the injection tables. In CI and GDI the maximum fuel injection is limited to prevent smoke formation, typically by tables, even though λ control can be and is partly used (Amstutz and del Re 1995).

In SI engines with port injection, the liquid fuel is injected near to the inlet valve and is expected to vaporize due to the local temperature and pressure conditions. During load changes, however, it can happen that part of the fuel is not vaporized, remains on the duct wall ("wall wetting"), and vaporizes at a later time, leading in both cases to a deviation from the expected values (Turin et al. 1995),

which must be compensated by the injection control.

Injection in CI engines is typically splitted in a main injection for torque and a pilot injection for NVH control and sometimes also a post-injection for emission control or regeneration of aftertreatment devices. Figure 4 shows the typical effect of a pilot injection on the pressure trace of a CI engine.

Differences between injectors of different cylinders are compensated by cylinder balancing control (typically using irregularities in the engine acceleration). Rail pressure is also an important control variable for the direct injection.

Ignition

Once the combustion chamber is filled, the combustion can be started. In SI and GDI combustion is started by a spark) leading to a flame front which propagates through the whole combustion chamber. Very few SI engines have a second spark plug to better control the combustion. Under some circumstances, e.g., high temperature, an undesired auto-ignition ("knock") can occur with potentially catastrophic consequences for the engine durability but also unconventional NVH. To cope with this, SI engines have vibration sensors whose output is used to modify the engine operation, in particular the spark timing, to prevent it.

In CI engines, the injection leads almost immediately to the combustion which has more the character of an explosion and starts typically at several undefined locations.

Additional control during the combustion is up to now only theoretically feasible, as the combustion takes place in an extremely short time, but also because adequate actuators are not available.

Aftertreatment

As the combustion mixture will always contain more potential reactants than oxygen and fuel, side reactions will always take place, yielding toxic products, in particular NOx, incompletely burnt fuel (HC), carbon monoxide (CO), and particulate matter (PM). Even if much effort is spent on reducing their formation, this is almost never sufficient, so additional aftertreatment equipment is used. Table 1 gives an overview over the most common aftertreatment systems as well as over their control aspects.

Thermal Management

All main properties of engines are strongly affected by its temperature, which depends on the varying load conditions. Engine operation is typically optimal for a relatively narrow temperature range, the same is even more critical for the exhaust aftertreatment system. Engine heat is also required for other purposes (like defrosting of windshields in cold climates).

Thus the engine control system has two main tasks: bringing the engine and the exhaust aftertreatment system as fast as possible into the target temperature range and taking in account deviation from this target. The first task is performed both by control of the cooling circuit and by specific combustion-related measures, the second one by taking the measured or estimated temperature as input for the controllers.

Fast heating is especially important for SI engines, because almost all toxic emissions are produced when the three-way catalyst is cold. To achieve faster heating, SI engines tend to operate in a less fuel efficient, but "hotter" operation mode during this warm-up phase, one of the causes of increased consumption of cold engines and short trips.

Cranking Idle Speed and Gear Shifting Control

Initially, the engine is cranked by the starter until a relatively low speed and then injection starts bringing the engine to the minimum operational speed. If the injected fuel is not immediately burnt, very high emissions will arise. At cranking, the cylinder walls are typically very cold and combustion of a stoichiometric mixture is hardly possible. So engine control has the task to inject as little as possible but as much as needed only in the cylinder which is going to fire.

Normally an ICE is expected to provide a torque to the driveline, speed being the result of the balance between it and the load. In idle control, no torque is transmitted to the driveline, but the engine speed is expected to remain stable in spite of possible changes of local loads (like cabin climate control). This boils down to a robust control problem (Hrovat and Sun 1997).

Engine Control, Table 1   Main exhaust aftertreatment systems

System	Purpose	Control targets
Three-way catalyst	Reduction of HC, CO, and NOx by more than 98 %	Achieve fast and maintain operating temperature and keep $\lambda = 1$
Oxydation catalyst	Reduction of HC and CO, partly of PM	Achieve fast and maintain operating temperature and keep $\lambda > 1$
Particulate filter	Traps PM	Check trap state and regenerate by increasing exhaust temperature for short time if needed
NOx lean trap	Traps NOx	Estimate trap state and shift combustion to CO rich when required
Selective catalyst reaction	Reduces NOx	Estimate required quantity of additional reactant (urea) and dose it

Gear shifting requires several steps. Smoothness and speed of the shifting depend on the coordination of engine operating point change. Actual hardware developments (double clutches, automated gear boxes) make a better operation, but require precise control.

New Trends

The utilization environment of engine control is changing. On one side, customer and legislator expectations continue producing pressure, but there is a shift in priority from emissions to fuel efficiency and safety. Driver support systems, for instance, automated parking, are becoming the longer the more pervasive, and many functions must be included or affect immediately the ECU, even though they are frequently hosted on own control hardware. Hybrid vehicles are gaining popularity, and this implies a different operation mode for the engine, for instance, thermal management becomes much more complex for range extender vehicles with long "cold" phases.

Maybe even more important is the diffusion of new devices and communication possibilities, so that, for instance, fuel saving preview-based gear shifting can be easily implemented using infrastructure-to-vehicle information, or even just navigation data. Further extensions, like cooperative adaptive cruise control (CACC), plan to use vehicle-to-vehicle information to increase both safety and efficiency.

Against this background, there is a growing consciousness that the actual industrial approach based on huge calibration work is becoming the longer the less viable and bears a steadily increasing risk of wasting potential performance. Some model-based controls have already found their way into the ECU, and the academy has shown in several occasions that model-based control is able to achieve better performance, but it has not yet been shown how this could comply with other industrialization requirements.

Actually, new faster sensors (e.g., pressure sensors in the combustion chambers) are being introduced; the interest in model-based control (Alberer et al. 2012) and in system identification

techniques (del Re et al. 2010) are increasing, but they are not yet widespread.

Estimation and Control over Networks

Vijay Gupta
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Estimation and control of systems when data is being transmitted across nonideal communication channels has now become an

important research topic. While much progress has been made in the area over the last few years, many open problems still remain. This entry summarizes some results available for such systems and points out a few open research directions. Two popular channel models are considered – the analog erasure channel model and the digital noiseless model. Results are presented for both the multichannel and multisensor settings.

Keywords

Analog erasure channel; Digital noiseless channel; Networked control systems; Sensor fusion

Introduction

Networked control systems refer to systems in which estimation and control is done across communication channels. In other words, these systems feature data transmission among the various components – sensors, estimators, controllers, and actuators – across communication channels that may delay, erase, or otherwise corrupt the data. It has been known for a long time that the presence of communication channels has deep and subtle effects. As an instance, an asymptotically stable linear system may display chaotic behavior if the data transmitted from the sensor to the controller and the controller to the actuator is quantized. Accordingly, the impact of communication channels on the estimation/control performance and design of estimation/control algorithms to counter any performance loss due to such channels have both become areas of active research.

Preliminaries

It is not possible to provide a detailed overview of all the work in the area. This entry attempts to summarize the flavor of the results that are available today. We focus on two specific communication channel models – analog erasure channel and the digital noiseless channel. Although other

channel models, e.g., channels that introduce delays or additive noise, have been considered in the literature, these models are among the ones that have been studied the most. Moreover, the richness of the field can be illustrated by concentrating on these models.

An analog erasure channel model is defined as follows. At every time step k, the channel supports as its input a real vector $i(k) \in \mathbf{R}^t$ with a bounded dimension t. The output $o(k)$ of the channel is determined stochastically. The simplest model of the channel is when the output is determined by a Bernoulli process with probability p. In this case, the output is given by

$$o(k) = \begin{cases} i(k-1) & \text{with probability } 1-p \\ \phi & \text{otherwise,} \end{cases}$$

where the symbol ϕ denotes the fact that the receiver does not obtain any data at that time step and, importantly, recognizes that the channel has not transmitted any data. The probability p is termed the erasure probability of the channel. More intricate models in which the erasure process is governed by a Markov chain, or by a deterministic process, have also been proposed and analyzed. In our subsequent development, we will assume that the erasure process is governed by a Bernoulli process.

A digital noiseless channel model is defined as follows. At every time step k, the channel supports at its input one out of 2^m symbols. The output of the channel is equal to the input. The symbol that is transmitted may be generated arbitrarily; however, it is natural to consider the channel as supporting m bits at every time step and the specific symbol transmitted as being generated according to an appropriately design quantizer. Once again, additional complications such as delays introduced by the channel have been considered in the literature.

A general networked control problem consists of a process whose states are being measured by multiple sensors that transmit data to multiple controllers. The controllers generate control inputs that are applied by different actuators. All the data is transmitted across communication

channels. Design of control inputs when multiple controllers are present, even without the presence of communication channels, is known to be hard since the control inputs in this case have dual effect. It is, thus, not surprising that not many results are available for networked control systems with multiple controllers. We will thus concentrate on the case when only one controller and actuator is present. However, we will review the known results for the analog erasure channel and the digital noiseless channel models when (i) multiple sensors observe the same process and transmit information to the controller and (ii) the sensor transmits information to the controller over a network of communication channels with an arbitrary topology.

An important distinction in the networked control system literature is that of one-block versus two-block designs. Intuitively, the one-block design arises from viewing the communication channel as a perturbation to a control system designed without a channel. In this paradigm, the only block that needs to be designed is the receiver. Thus, for instance, if an analog erasure channel is present between the sensor and the estimator, the sensor continues to transmit the measurements as if no channel is present. However, the estimator present at the output of the channel is now designed to *compensate* for any imperfections introduced by the communication channel. On the other hand, in the two-block design paradigm, both the transmitter and the receiver are designed to optimize the estimation or control performance. Thus, if an analog erasure channel is present between the sensor and the estimator, the sensor can now transmit an appropriate function of the information it has access to. The transmitted quantity needs to satisfy the constraints introduced by the channel in terms of the dimensions, bit rate, power constraints, and so on. It is worth remembering that while the two-block design paradigm follows in spirit from communication theory where both the transmitter and the receiver are design blocks, the specific design of these blocks is usually much more involved than in communication theory. It is not surprising that in general performance with

two-block designs is better than the one-block designs.

Analog Erasure Channel Model

Consider the usual LQG formulation. A linear process of the form

$$x(k+1) = Ax(k) + Bu(k) + w(k),$$

with state $x(k) \in \mathbf{R}^d$ and process noise $w(k)$ is controlled using a control input $u(k) \in \mathbf{R}^m$. The process noise is assumed to be white, Gaussian, zero mean, with covariance Σ_w. The initial condition $x(0)$ is also assumed to be Gaussian and zero mean with covariance Π_0. The process is observed by n sensors, with the i-th sensor generating measurements of the form

$$y_i(k) = C_i x(k) + v_i(k),$$

with the measurement noise $v_i(k)$ assumed to be white, Gaussian, zero mean, with covariance Σ_v^i. All the random variables in the system are assumed to be mutually independent. We consider two cases:

- If $n = 1$, the sensor communicates with the controller across a network consisting of multiple communication channels connected according to an arbitrary topology. Every communication channel is modeled as an analog erasure channel with possibly a different erasure probability. The erasure events on the channels are assumed to be independent of each other, for simplicity. The sensor and the controller then form two nodes of a network each edge of which represents a communication channel.
- If $n > 1$, then every sensor communicates with the controller across an individual communication channel that is modeled as an analog erasure channel with possibly a different erasure probability. The erasure events on the channels are assumed to be independent of each other, for simplicity.

The controller calculates the control input to optimize a quadratic cost function of the form

$$J_K = E\left[\sum_{k=0}^{K-1} \left(x^T(k)Qx(k) + u^T(k)Ru(k) \right) \right.$$

$$\left. + x^T(K)P_Kx(K) \right].$$

All the covariance matrices and the cost matrices Q, R, and P_K are assumed to be positive definite. The pair (A, B) is controllable and the pair (A, C) is observable, where C is formed by stacking the matrices C_i's. The system is said to be stabilizable if there exists a design (within the specified one-block or two-block design framework) such that the cost $\lim_{K\to\infty} \frac{1}{K} J_K$ is bounded.

A Network of Communication Channels

We begin with the case when $N = 1$ as mentioned above. The one-block design problem in the presence of a network of communication channels is identical to the one-block design as if only one channel were present. This is because the network can be replaced by an "equivalent" communication channel with the erasure probability as some function of the reliability of the network. This can lead to poor performance, since the reliability may decrease quickly as the network size increases. For this reason, we will concentrate on the two-block design paradigm.

The two-block design paradigm permits the nodes of the network to process the data prior to transmission and hence achieve much better performance. The only constraint imposed on the transmitter is that the quantity that is transmitted is a causal function of the information that the node has access to, with a bounded dimension. The design problem can be solved using the following steps. The first step is to prove that a separation principle holds if the controller knows the control input applied by the actuator at every time step. This can be the case if the controller transmits the control input to the actuator across a perfect channel or if the control input is transmitted across an analog erasure channel but the actuator can transmit an acknowledgment to the controller. For simplicity, we assume that the controller transmits the control input to the actuator across a perfect channel. The separation principle states that the optimal performance is achieved if the control input is calculated using the usual LQR control law, but the process state is replaced by the minimum mean squared error (MMSE) estimate of the state. Thus, the two-block design problem needs to be solved now for an optimal *estimation* problem.

The next step is to realize that for any allowed two-block design, an upper bound on estimation performance is provided by the strategy of every node transmitting every measurement it has access to at each time step. Notice that this strategy is not in the set of allowed two-block designs since the dimension of the transmitted quantity is not bounded with time. However, the same estimate is calculated at the decoder if the sensor transmits an estimate of the state at every time step and every other node (including the decoder) transmits the latest estimate it has access to from either its neighbors or its memory. This algorithm is recursive and involves every node transmitting a quantity with bounded dimension, however, since it leads to calculation of the same estimate at the decoder, and is, thus, optimal. It is worth remarking that the intermediate nodes do not require access to the control inputs. This is because the estimate at the decoder is a linear function of the control inputs and the measurements: thus, the effect of control inputs in the estimate can be separated from the effect of the measurements and included at the controller. Moreover, as long as the closed loop system is stable, the quantities transmitted by various nodes are also bounded. Thus, the two-block design problem can be solved.

The stability and performance analysis with the optimal design can also be performed. As an example, a necessary and sufficient stabilizability condition is that the inequality

$$p_{\text{maxcut}}\rho(A)^2 < 1,$$

holds, where $\rho(A)$ is the spectral radius of A and p_{maxcut} is the max-cut probability evaluated as follows. Generate cut-sets from the network by dividing the nodes into two sets – a source

set containing the sensor and a sink set containing the controller. For each cut-set, obtain the cut-set probability by multiplying the erasure probabilities of the channels from the source set to the sink set. The max-cut probability is the maximum such cut-set probability. The necessity of the condition follows by recognizing that the channels from the source set to the sink set need to transmit data at a high enough rate even if the channels within each set are assumed not to erase any data. The sufficiency of the condition follows by using the Ford-Fulkerson algorithm to reduce the network into a collection of parallel paths from the sensor to the controller such that each path has links with equal erasure probability and the product of these probabilities for all paths is the max-cut probability. More details can be found in Gupta et al. (2009a).

Multiple Sensors

Let us now consider the case when the process is observed using multiple sensors that transmit data to a controller across an individual analog erasure channel. A separation principle to reduce the control design problem into the combination of an LQR control law and an estimation problem can once again be proven. Thus, the two-block design for the estimation problem asks the following question: what quantity should the sensors transmit such that the decoder is able to generate the optimal MMSE estimate of the state at every time step, given all the information the decoder has received till that time step. This problem is similar to the track-to-track fusion problem that has been studied since the 1980s and is still open for general cases (Chang et al. 1997). Suppose that at time k, the last successful transmission from sensor i happened at time $k_i \leq k$. The optimal estimate that the decoder can ever hope to achieve is the estimate of the state $x(k)$ based on all measurements from the sensor 1 till time k_1, from sensor 2 till time k_2, and so on. However, it is not known whether this estimate is achievable if the sensors are constrained to transmit real vectors with a bounded dimension. A fairly intuitive encoding scheme is if the sensors transmit the *local* estimates of the state based on their own measurements. However,

it is known that the *global* estimate cannot, in general, be obtained from local estimates because of the correlation introduced by the process noise. If erasure probabilities are zero, or if the process noise is not present, then the optimal encoding schemes are known. Another case for which the optimal encoding schemes are known is when the estimator sends back acknowledgments to the encoders.

Transmitting local estimates does, however, achieve optimal stability conditions as compared to the conditions obtained from the optimal (unknown) two-block design (Gupta et al. 2009b). As an example, the necessary and sufficient stability conditions for the two sensor cases are given by

$$p_1 \rho(A_1)^2 < 1$$
$$p_2 \rho(A_2)^2 < 1$$
$$p_1 p_2 \rho(A_3)^2 < 1,$$

where p_1 and p_2 are erasure probabilities from sensors 1 and 2, respectively, $\rho(A_1)$ is the spectral radius of the unobservable part of the matrix A from the second sensor, $\rho(A_2)$ is the spectral radius of the unobservable part of the matrix A from the first sensor, and $\rho(A_3)$ is the spectral radius of the observable part of the matrix A from both the sensors. The conditions are fairly intuitive. For instance, the first condition provides a bound on the rate of increase of modes for which only sensor 1 can provide information to the controller, in terms of how reliable the communication channel from the sensor 1 is.

Digital Noiseless Channels

Similar results as above can be derived for the digital noiseless channel model. For the digital noiseless channel model, it is easier to consider the system without either measurement or process noises (although results with such noises are available). Moreover, since quantization is inherently highly nonlinear, results such as separation between estimation and control are not available. Thus, encoders and controllers that optimize a

cost function such as a quadratic performance metric are not available even for the single sensor or channel case. Most available results thus discuss stabilizability conditions for a given data rate that the channels can support.

While early works used the one-block design framework to model the digital noiseless channel as introducing an additive white quantization noise, that framework obscures several crucial features of the channel. For instance, such an additive noise model suggests that at any bit rate, the process can be stabilized by a suitable controller. However, a simple argument can show that is not true. Consider a scalar process in which at time k, the controller knows that the state is within a set of length $l(k)$. Then, stabilization is possible only if $l(k)$ remains bounded as $k \to \infty$. Now, the evolution of $l(k)$ is governed by two processes: at every time step, this uncertainty can be (i) decreased by a factor of at most 2^m due to the data transmission across the channel and (ii) increased by a factor of a (where a is the process matrix governing the evolution of the state) due to the process evolution. This implies that for stabilization to be possible, the inequality $m \geq \log_2(a)$ must hold. Thus, the additive noise model is inherently wrong. Most results in the literature formalize this basic intuition above (Nair et al. 2007).

A Network of Communication Channels
For the case when there is only one sensor that transmits information to the controller across a network of communication channels connected in arbitrary topology, an analysis similar to that done for analog erasure channels can be performed (Tatikonda 2003). A max-flow min-cut like theorem again holds. The stability condition now becomes that for any cut-set

$$\sum R_j > \sum_{\text{all unstable eigenvalues}} \log_2(\lambda_i),$$

where $\sum R_j$ is the sum of data rates supported by the channels joining the source set to sink set for any cut-set and λ_i are the eigenvalues of the process matrix A. Note that the summation on the right hand side is only over the unstable eigenvalues, since no information needs to be transmitted about the modes that are stable in open loop.

Multiple Sensors
The case when multiple sensors transmit information across an individual digital noiseless channel to a controller can also be considered. For every sensor i, define a rate vector $\{R_{i_1}, R_{i_2}, \cdots, R_{i_d}\}$ corresponding to the d modes of the system. If a mode j cannot be observed from the sensor i, set $R_{i_j} = 0$. For stability, the condition

$$\sum_i R_{ij} \geq \max(0, \lambda_j),$$

for every mode j must be satisfied. All such rate vectors stabilize the system.

Summary and Future Directions

This entry provided a brief overview of some results available in the field of networked control systems. Although the area is seeing intense research activity, many problems remain open. For control across analog erasure channels, most existing results break down if a separation principle cannot be proved. Thus, for example, if control packets are also transmitted to the actuator across an analog erasure channel, the LQG optimal two-block design is unknown. There is some recent work on analyzing the stabilizability under such conditions (Gupta and Martins 2010), but the problem remains open in general. For digital noiseless channels, controllers that optimize some performance metric are largely unknown. Considering more general channel models is also an important research direction (Martins and Dahleh 2008; Sahai and Mitter 2006).

Estimation for Random Sets

Ronald Mahler
Eagan, MN, USA

Abstract

The random set (RS) concept generalizes that of a random vector. It permits the mathematical modeling of random systems that can be interpreted as random patterns. Algorithms based on RSs have been extensively employed in image processing. More recently, they have found application in multitarget detection and tracking and in the modeling and processing of human-mediated information sources. The purpose of this entry is to briefly summarize the concepts, theory, and practical application of RSs.

Keywords

Introduction

In ordinary signal processing, one models physical phenomena as "sources," which generate "signals" obscured by random "noise." The sources are to be extracted from the noise using optimal-estimation algorithms. Random set (RS) theory was devised about 40 years ago by mathematicians who also wanted to construct optimal-estimation algorithms. The "signals" and "noise" that they had in mind, however, were *geometric patterns in images*. The resulting theory, *stochastic geometry*, is the basis of the "morphological operators" commonly employed today in image-processing applications. It is also the basis for the theory of RSs. An important special case of RS theory, the theory of *random finite sets* (RFSs), addresses problems in which the patterns of interest consist of a finite number of points. It is the theoretical basis of many modern medical and other image-processing algorithms. In recent years, RFS theory has found application to the problem of detecting, localizing, and tracking unknown numbers of unknown, evasive point targets. Most recently and perhaps most surprisingly, RS theory provides a theoretically rigorous way of addressing "signals" that are *human-mediated*, such as natural-language statements and inference rules. The breadth of RS theory is suggested in the various chapters of Goutsias et al. (1997).

The purpose of this entry is to summarize the RS and RFS theories and their applications. It is divided in to the following sections: A Simple Example, Mathematics of Random Sets, Random Sets and Image Processing, Random Sets and Multitarget Processing, Random Sets and Human-Mediated Data, Summary and Future Directions, Cross-References, and Recommended Reading.

A Simple Example

To illustrate the concept of a RS, let us begin by examining a simple example: *locating stars in the nighttime sky*. We will proceed in successively more illustrative steps:

Locating a single non-dim star (estimating a random point). When we try to locate a star, we are trying to estimate its actual position – its "state" $\mathbf{x} = (\alpha_0, \theta_0)$ – in terms of its azimuth angle α_0 and elevation angle θ_0. When the star is dim but not too dim, its apparent position will vary slightly. We can estimate its position by averaging many measurements – i.e., by applying a *point estimator*.

Locating a very dim star (estimating an RS with at most one element). Assume that the star is so dim that, when we see it, it might be just a momentary visual illusion. Before we can estimate its position, we must *first estimate whether or not it exists*. We must record not only its apparent position $\mathbf{z} = (\alpha, \theta)$ (if we see it) but its *apparent existence* ε, with $\varepsilon = 1$ (we saw it) or $\varepsilon = 0$ (we did not). Averaging ε over many observations, we get a number q between 0 and 1. If $q > \frac{1}{4}$ (say), we could declare that the star probably actually is a star; and then we could average the non-null observations to estimate its position.

Locating multiple stars (estimating an RFS). Suppose that we are trying to locate *all* of the stars in some patch of sky. In some cases, two dim stars may be so close that they are difficult to distinguish. We will then collect three kinds of measurements from them: $Z = \emptyset$ (did not see either star), $Z = \{(\alpha, \theta)\}$ (we saw one or the other), or $Z = \{(\alpha_1, \theta_1), (\alpha_2, \theta_2)\}$ (saw both). The total collected measurement in the patch of sky is a finite set $Z = \{\mathbf{z}_1, \ldots, \mathbf{z}_m\}$ of point measurements with $\mathbf{z}_j = (\theta_j, \alpha_j)$, where each $\mathbf{z}_i$ is random, where m is random, and where $m = 0$ corresponds to the null measurement $Z = \emptyset$.

Locating multiple stars in a quantized sky (estimation using imprecise measurements). Suppose that, for computational reasons, the patch of sky must be quantized into a finite number of hexagonal-shaped cells, $c_1, \ldots, c_M$. Then, the measurement from any star is not a specific point $\mathbf{z}$, but instead the cell c that contains $\mathbf{z}$. The measurement c is *imprecise* – a randomly varying hexagonal cell c. There are two ways of thinking about the total measurement collection. First, it is a finite set $Z = \{c_1', \ldots, c_m'\} \subseteq \{c_1, \ldots, c_M\}$ of cells. Second, it is the union $Z = c_1' \cup \ldots \cup c_m'$ of all of the observed cells – i.e., it is a *geometrical pattern*.

Locating multiple stars over an extended period of time (estimating multiple moving targets). As the night progresses, we must continually redetermine the existence and positions of each star – a process called *multitarget tracking*. We must also account for appearances and disappearances of the stars in the patch – i.e., for *target death and birth*.

Mathematics of Random Sets

The purpose of this section is to sketch the elements of the theory of random sets. It is organized as follows: General Theory of Random Sets, Random Finite Sets (Random Point Processes), and Stochastic Geometry. Of necessity, the material is less elementary than in later sections.

General Theory of Random Sets

Let $\mathfrak{Y}$ be a topological space – for example, an N-dimensional Euclidean space $\mathbb{R}^N$. The *power set* $2^{\mathfrak{Y}}$ of $\mathfrak{Y}$ is the class of all possible subsets $S \subseteq \mathfrak{Y}$. Any subclass of $2^{\mathfrak{Y}}$ is called a "hyperspace." The "elements" or "points" of a hyperspace are thus actually subsets of some other space. For a hyperspace to be of interest, one must extend the topology on $\mathfrak{Y}$ to it. There are many possible topologies for hyperspaces (Michael 1950). The most well studied is the *Fell-Matheron topology*, also called the "hit-and-miss" topology (Matheron 1975). It is applicable when $\mathfrak{Y}$ is Hausdorff, locally compact, and completely separable. It topologizes only the hyperspace $\mathfrak{c}(2^{\mathfrak{Y}})$ of all *closed* subsets C of $\mathfrak{Y}$. In this case, a *random* (closed) *set* Θ is a measurable mapping from some probability space into $\mathfrak{c}(2^{\mathfrak{Y}})$.

The Fell-Matheron topology's major strength is its relative simplicity. Let "$\Pr(\mathcal{E})$" denote the probability of a probabilistic event $\mathcal{E}$. Then, normally, the probability law of Θ would be

described by a very abstract probability measure $p_\Theta(O) = \Pr(\Theta \in O)$. This measure must be defined on the Borel-measurable subsets $O \subseteq \mathfrak{c}(2^{\mathfrak{Y}})$, with respect to the Fell-Matheron topology, where O is itself a class of subsets of $\mathfrak{Y}$. However, define the *Choquet capacity functional* by $c_\Theta(G) = \Pr(\Theta \cap G \neq \emptyset)$ for all open subsets $G \subseteq \mathfrak{Y}$. Then, the *Choquet-Matheron theorem* states that the probability law of Θ is completely described by the simpler, albeit nonadditive, measure $c_\Theta(G)$.

The theory of random sets has evolved into a substantial subgenre of statistical theory (Molchanov 2005). For estimation theory, the concept of the *expected value* $\mathbb{E}[\Theta]$ of a random set Θ is of particular interest. Most definitions of $\mathbb{E}[\Theta]$ are very abstract (Molchanov 2005, Chap. 2). In certain circumstances, however, more conventional-looking definitions are possible. Suppose that $\mathfrak{Y}$ is a Euclidean space and that $\mathfrak{c}(2^{\mathfrak{Y}})$ is restricted to $\mathfrak{K}(2^{\mathfrak{Y}})$, the *bounded, convex, closed subsets* of $\mathfrak{Y}$. If C, C' are two such subsets, their *Minkowski sum* is $C + C' = \{c + c' \mid c \in C, c' \in C'\}$. Endowed with this definition of addition, $\mathfrak{K}(2^{\mathfrak{Y}})$ can be homeomorphically and homomorphically embedded into a certain space of functions (Molchanov 2005, pp. 199–200). Denote this embedding by $C \longmapsto \phi_C$. Then, the expected value $\mathbb{E}[\Theta]$ of Θ, defined in terms of Minkowski addition, corresponds to the *conventional* expected value $\mathbb{E}[\phi_\Theta]$ of the random function ϕ_Θ.

Random Finite Sets (Random Point Processes)

Suppose that the $\mathfrak{c}(2^{\mathfrak{Y}})$ is restricted to $\mathfrak{f}(2^{\mathfrak{Y}})$, the class of *finite* subsets of $\mathfrak{Y}$. (In many formulations, $\mathfrak{f}(2^{\mathfrak{Y}})$ is taken to be the class of *locally finite* subsets of $\mathfrak{Y}$ – i.e., those whose intersection with compact subsets is finite.) A *random finite set* (RFS) is a measurable mapping from a probability space into $\mathfrak{f}(2^{\mathfrak{Y}})$. An example: the field of twinkling stars in some patch of a night sky. RFS theory is a particular mathematical formulation of *point process theory* (Daley and Vere-Jones 1998; Snyder and Miller 1991; Stoyan et al. 1995).

A *Poisson RFS* Ψ is perhaps the simplest nontrivial example of a random point pattern. It is specified by a *spatial distribution* $s(\mathbf{y})$ and an *intensity* μ. At any given instant, the probability that there will be n points in the pattern is $p(n) = e^{-\mu} \mu^n / n!$ (the value of the Poisson distribution). The probability that one of these n points will be $\mathbf{y}$ is $s(\mathbf{y})$. The function $D_\Psi(\mathbf{y}) = \mu \cdot s(\mathbf{y})$ is called the *intensity function* of Ψ.

At any moment, the point pattern produced by Ψ is a finite set $Y = \{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$ of points $\mathbf{y}_1, \ldots, \mathbf{y}_n$ in $\mathfrak{Y}$, where $n = 0, 1, \ldots$ and where $Y = \emptyset$ if $n = 0$. If $n = 0$ then Y represents the hypothesis that no objects at all are present. If $n = 1$ then $Y = \{\mathbf{y}_1\}$ represents the hypothesis that a single object $\mathbf{y}_1$ is present. If $n = 2$ then $Y = \{\mathbf{y}_1, \mathbf{y}_2\}$ represents the hypothesis that there are two distinct objects $\mathbf{y}_1 \neq \mathbf{y}_2$. And so on.

The *probability distribution* of Ψ – i.e., the probability that Ψ will have $Y = \{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$ as an instantiation – is entirely determined by its intensity function $D_\Psi(\mathbf{y})$:

$$\begin{aligned} f_\Psi(Y) &= f_\Psi(\{\mathbf{y}_1, \ldots, \mathbf{y}_n\}) \\ &= e^{-mu} \cdot D_\Psi(\mathbf{y}_1) \cdots D_\Psi(\mathbf{y}_n) \end{aligned}$$

Every suitably well-behaved RFS Ψ has a probability distribution $f_\Psi(Y)$ and an intensity function $D_\Psi(\mathbf{y})$ (a.k.a. *first-moment density*). A Poisson RFS is unique in that $f_\Psi(Y)$ is completely determined by $D_\Psi(\mathbf{y})$.

Conventional signal processing is often concerned with single-object random systems that have the form

$$\mathbf{Z} = \eta(\mathbf{x}) + \mathbf{V}$$

where $\mathbf{x}$ is the state of the system; $\eta(\mathbf{x})$ is the "signal" generated by the system; the zero-mean random vector $\mathbf{V}$ is the random "noise" associated the sensor; and $\mathbf{Z}$ is the random measurement that is observed. The purpose of signal processing is to construct an estimate $\hat{\mathbf{x}}(\mathbf{z}_1, \ldots, \mathbf{z}_k)$ of $\mathbf{x}$, using the information contained in one or more draws $\mathbf{z}_1, \ldots, \mathbf{z}_k$ from the random variable $\mathbf{Z}$.

RFS theory is analogously concerned with random systems that have the form

$$\Sigma = \Upsilon(X) \cup \Omega$$

where a random finite point pattern $\Upsilon(X)$ is the "signal" generated by the point pattern X (which is an instantiation of a random point pattern Ξ); Ω is a random finite point "noise" pattern; Σ is the total random finite point pattern that has been observed; and "$\cup$" denotes set-theoretic union. One goal of RFS theory is to devise algorithms that can construct an estimate $\hat{X}(Z_1, \ldots, Z_k)$ of X, using multiple point patterns $Z_1, \ldots, Z_k \subseteq \mathfrak{Y}$ drawn from Σ. One approximate approach is that of estimating only the first-moment density $D_\Xi(\mathbf{x})$ of Ξ.

Stochastic Geometry

Stochastic geometry addresses more complicated random patterns. An example: the field of twinkling stars in a *quantized* patch of the night sky, in which case the measurement is the union $c_1 \cup \ldots \cup c_m$ of a finite number of hexagonally shaped cells.

This is one instance of a *germ-grain process* (Stoyan et al. 1995, pp. 59–64). Such a process is specified by two items: an RFS Ψ and a function $c_\mathbf{y}$ that associates with each $\mathbf{y}$ in $\mathfrak{Y}$ a closed subset $c_\mathbf{y} \subseteq \mathfrak{Z}$. For example, if $\mathfrak{Y} = \mathbb{R}^2$ is the real-valued plane, then $c_\mathbf{y}$ could be the disk of radius r centered at $\mathbf{y} = (x, y)$. Let $Y = \{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$ be a particular random draw from Ψ. The points $\mathbf{y}_1, \ldots, \mathbf{y}_n$ are the "germs," and $c_{\mathbf{y}_1}, \ldots, c_{\mathbf{y}_n}$ are the "grains" of this random draw from the germ-grain process Θ. The total pattern in $\mathfrak{Y}$ is the union $c_{\mathbf{y}_1} \cup \ldots \cup c_{\mathbf{y}_n}$ of the grains – a random draw from Θ. Germ-grain processes can be used to model many kinds of natural processes. One example is the distribution of graphite particles in a two-dimensional section of a piece of iron, in which case the $c_\mathbf{y}$ could be chosen to be line segments rather than disks.

Stochastic geometry is concerned with random binary images that have observation structures such as

$$\Theta = (S \cap \Delta) \cup \Omega$$

where S is a "signal" pattern; Δ is a random pattern that models obscurations; Ω is a random pattern that models clutter; and Θ is the total pattern that has been observed. A common simplifying assumption is that Ω and Δ^c are germ-grain processes. One goal of stochastic geometry is to devise algorithms that can construct an optimal estimate $\hat{S}(T_1, \ldots, T_k)$ of S, using multiple patterns $T_1, \ldots, T_k \subseteq \mathfrak{Y}$ drawn from Θ.

Random Sets and Image Processing

Both point process theory and stochastic geometry have found extensive application to image-processing applications. These are considered briefly in turn.

Stochastic Geometry and Image Processing. Stochastic geometry methods are based on the use of a "structuring element" B (a geometrical shape, such as a disk, sphere, or more complex structure) to modify an image.

The *dilation* of a set S by B is $S \oplus B$ where "$\oplus$" is Minkowski addition (Stoyan et al. 1995). Dilation tends to fill in cavities and fissures in images. The *erosion* of S is $S \ominus B = (S^c \oplus B^c)^c$ where "^{c}" indicates set-theoretic complement. Erosion tends to create and increase the size of cavities and fissures. *Morphological filters* are constructed from various combinations of dilation and erosion operators.

Suppose that a binary image $\Sigma = S$ has been degraded by some measurement process – for example, the process $\Theta = (S \cap \Delta) \cup \Omega$. Then, *image restoration* refers to the construction of an estimate $\hat{S}(T)$ of the original image S from a single degraded image $\Theta = T$. The restoration operator $\hat{S}(T)$ is *optimal* if it can be shown to be optimally close to S, given some concept of closeness. The *symmetric difference*

$$T_1 \sqcup T_2 = (T_1 \cup T_2) - (T_1 \cap T_2)$$

is a commonly used method for measuring the dissimilarity of binary images. It can be used to construct measures of distance between random images. One such distance is

$$d(\Theta_1, \Theta_2) = \mathbb{E}\left[|\Theta_1 \sqcup \Theta_2|\right]$$

where $|S|$ denotes the size of the set S and $\mathbb{E}[A]$ is the expected value of the random number A. Other distances require some definition of the expected value $\mathbb{E}[\Theta]$ of a random set Θ. It has been shown that, under certain circumstances, certain morphological operators can be viewed as consistent maximum a posteriori (MAP) estimators of S (Goutsias et al. 1997, p. 97).

RFS Theory and Image Processing. Positron-emission tomography (PET) is one example of the application of RFS theory. In PET, tissues of interest are suffused with a positron-emitting radioactive isotope. When a positron annihilates an electron in a suitable fashion, two photons are emitted in opposite directions. These photons are detected by sensors in a ring surrounding the radiating tissue. The location of the annihilation on the line can be estimated by calculating time difference of arrival.

Because of the physics of radioactive decay, the annihilations can be accurately modeled as a Poisson RFS Ψ. Since a Poisson RFS is completely determined by its intensity function $D_\Psi(\mathbf{x})$, it is natural to try to estimate $D_\Psi(\mathbf{x})$. This yields the spatial distribution $s_\Psi(\mathbf{y})$ of annihilations – which, in turn, is the basis of the PET image (Snyder and Miller 1991, pp. 115–119).

Random Sets and Multitarget Processing

The purpose of this section is to summarize the application of RFS theory to multitarget detection, tracking, and localization. An example: tracking the positions of stars in the night sky over an extended period of time.

Suppose that at time t_k there are an unknown number n of targets with unknown states $\mathbf{x}_1, \ldots, \mathbf{x}_n$. The state of the entire multitarget system is a finite set $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$ with $n \geq 0$. When interrogating a scene, many sensors (such as radars) produce a measurement of the form $Z = \{\mathbf{z}_1, \ldots, \mathbf{z}_m\}$ – i.e., a finite set of measurements. Some of these measurements are generated by background

clutter Ω_k. Others are generated by the targets, with some targets possibly not having generated any. Mathematically speaking, Z is a random draw from an RFS Σ_k that can be decomposed as $\Sigma_k = \Upsilon(X_k) \cup \Omega_k$, where $\Upsilon(X_k)$ is the set of target-generated measurements.

Conventional Multitarget Detection and Tracking. This is based on a "divide and conquer" strategy with three basic steps: *time update*, *data association*, and *measurement update*. At time t_k we have n "tracks" $\tau_1, \ldots, \tau_n$ (hypothesized targets). In the time update, an extended Kalman filter (EKF) is used to time-predict the tracks τ_i to *predicted tracks* τ_i^+ at the time t_{k+1} of the next measurement set $Z_{k+1} = \{\mathbf{z}_1, \ldots, \mathbf{z}_m\}$.

Given Z_{k+1}, we can construct the following *data-association hypothesis H*: for each $i = 1, \ldots, n$, the predicted track τ_i^+ generated the detection $\mathbf{z}_{j_i}$, for some index j_i, or, alternatively, this track was not detected at all. If we remove from Z_{k+1} all of the $\mathbf{z}_{j_1}, \ldots, \mathbf{z}_{j_n}$, the remaining measurements are interpreted either as being clutter or as having been generated by new targets. Enumerating all possible association hypotheses (which is a combinatorily complex procedure), we end up with a "hypothesis table" $H_1, \ldots, H_\nu$.

Given H_i, let $\mathbf{z}_{j_i}$ be the measurement that is hypothesized to have been generated by predicted track τ_i^+. Then, the measurement-update step of an EKF is used to construct a measurement-updated track τ_{i,j_i} from τ_i^+ and $\mathbf{z}_{j_i}$. Attached to each H_i is a *hypothesis probability p_i* – the probability that the particular hypothesis H_i is the correct one. The hypothesis with largest p_i yields the multitarget estimate $\hat{X} = \{\hat{\mathbf{x}}_1, \ldots, \hat{\mathbf{x}}_{\hat{n}}\}$.

RFS Multitarget Detection and Tracking. In the place of tracks and hypothesis tables, this uses *multitarget state sets* and *multitarget probability distributions*. In place of the conventional time update, data association, and measurement update, it uses a *recursive Bayes filter*. A random multitarget state set is an RFS $\Xi_{k|k}$ whose points are target states. A multitarget probability distribution is the probability distribution $f(X_k|Z_{1:k}) = f_{\Xi_{k|k}}(X)$ of the RFS $\Xi_{k|k}$,

where $Z_{1:k} : Z_1, \ldots, Z_k$ is the time sequence of measurement sets at time t_k.

RFS Time Update. The Bayes filter time-update step $f(X_k|Z_{1:k}) \rightarrow f(X_{k+1}|Z_{1:k})$ requires a *multitarget Markov transition function* $f(X_{k+1}|X_k)$. It is the probability that the multitarget system will have multitarget state set X_{k+1} at time t_{k+1}, if it had multitarget state set X_k at time t_k. It takes into account all pertinent characteristics of the targets: individual target motion, target appearance, target disappearance, environmental constraints, etc. It is explicitly constructed from an *RFS multitarget motion model* using a *multitarget integrodifferential calculus*.

RFS Measurement Update. The Bayes filter measurement-update step $f(X_{k+1}|Z_{1:k}) \rightarrow f(X_{k+1}|Z_{1:k+1})$ is just Bayes rule. It requires a *multitarget likelihood function* $f_{k+1}(Z|X)$ – the likelihood that a measurement set Z will be generated, if a system of targets with state set X is present. It takes into account all pertinent characteristics of the sensor(s): sensor noise, fields of view and obscurations, probabilities of detection, false alarms, and/or clutter. It is explicitly constructed from an *RFS measurement model* using multitarget calculus.

RFS State Estimation. Determination of the number n and states $\mathbf{x}_1, \ldots, \mathbf{x}_n$ of the targets is accomplished using a *Bayes-optimal multitarget state estimator*. The idea is to determine the X_{k+1} that maximizes $f(X_{k+1}|Z_{1:k+1})$ in some sense.

Approximate Multitarget RFS Filters. The multitarget Bayes filter is, in general, computationally intractable. Central to the RFS approach is a toolbox of techniques – including the multitarget calculus – designed to produce *statistically principled* approximate multitarget filters. The two most well studied are the *probability hypothesis density* (PHD) *filter* and its generalization the *cardinalized PHD* (CPHD) *filter*. In such filters, $f(X_k|Z_{1:k})$ is replaced by the first-moment density $D(\mathbf{x}_k|Z_{1:k})$ of $\Xi_{k|k}$. These filters have been shown to be faster and

perform better than conventional approaches in some applications.

Random Sets and Human-Mediated Data

Random Sets and Human-Mediated Data

Natural-language statements and inference rules have already been mentioned as examples of human-mediated information. *Expert-systems theory* was introduced in part to address situations – such as this – that involve uncertainties other than randomness. Expert-system methodologies include *fuzzy set theory*, the *Dempster-Shafer* (D-S) *theory of uncertain evidence*, and *rule-based inference*. RS theory provides solid Bayesian foundations for them and allows human-mediated data to be processed using standard Bayesian estimation techniques. The purpose of this section is to briefly summarize this aspect of the RS approach.

The relationships between expert-systems theory and random set theory were first established by researchers such as Orlov (1978), Höhle (1982), Nguyen (1978), and Goodman and Nguyen (1985). At a relatively early stage, it was recognized that random set theory provided a potential means of unifying much of expert-systems theory (Goodman and Nguyen 1985; Kruse et al. 1991).

A conventional sensor measurement at time t_k is typically represented as $\mathbf{Z}_k = \eta(\mathbf{x}_k) + \mathbf{V}_k$ – equivalently formulated as a *likelihood function* $f(\mathbf{z}_k|\mathbf{x}_k)$. It is conventional to think of $\mathbf{z}_k$ as the actual "measurement" and of $f(\mathbf{z}_k|\mathbf{x}_k)$ as the full description of the uncertainty associated with it. In actuality, $\mathbf{z}_k$ is just a *mathematical model* $\mathbf{z}_{\zeta_k}$ of some *real-world measurement* ζ_k. Thus, the likelihood actually has the form $f(\zeta_k|\mathbf{x}_k) = f(\mathbf{z}_{\zeta_k}|\mathbf{x}_k)$.

This observation assumes crucial importance when one considers human-mediated data. Consider the simple natural-language statement

$$\zeta = \text{``The target is near the tower''}$$

where the *tower* is a landmark, located at a known position (x_0, y_0), and where the term "near" is assumed to have the following specific meaning: (x, y) is near (x_0, y_0) means that $(x, y) \in T_5$ where T_5 is a disk of radius $5\,$m, centered at (x_0, y_0). If $\mathbf{z} = (x, y)$ is the actual measurement of the target's position, then ζ is *equivalent to the formula* $\mathbf{z} \in T_5$. Since $\mathbf{z}$ is just one possible draw from $\mathbf{Z}_k$, we can say that ζ – or, equivalently, T_5 – is actually a constraint on the underlying measurement process: $\mathbf{Z}_k \in T_5$.

Because the word "near" is rather vague, we could just as well say that $\mathbf{z} \in T_5$ is the best choice, with confidence $w_5 = 0.7$; that $\mathbf{z} \in T_4$ is the next best choice, with confidence $w_4 = 0.2$; and that $\mathbf{z} \in T_6$ is the least best, with confidence $w_6 = 0.1$. Let Θ be the random subset of $\mathfrak{Z}$ defined by $\Pr(\Theta = T_i) = w_i$ for $i = 4, 5, 6$. In this case, ζ is equivalent to the *random constraint*

$$\mathbf{Z}_k \in \Theta.$$

The probability

$$\rho_k(\Theta | \mathbf{x}_k) = \Pr(\eta(\mathbf{x}_k) + \mathbf{V}_k \in \Theta)$$
$$= \Pr(\mathbf{Z}_k \in \Theta | \mathbf{X}_k = \mathbf{x}_k)$$

is called a *generalized likelihood function* (GLF). GLFs can be constructed for more complex natural-language statements, for inference rules, and more. Using their GLF representations, such "nontraditional measurements" can be processed using single- and multi-object recursive Bayes filters and their approximations. As a consequence, it can be shown that fuzzy logic, the D-S theory, and rule-based inference can be subsumed within a single Bayesian-probabilistic paradigm.

Summary and Future Directions

In the engineering world, the theory of random sets has been associated primarily with certain specialized image-processing applications, such as morphological filters and tomographic imaging. It has more recently found application in fields such as multitarget tracking and in expert-systems theory. All of these fields of application remain areas of active research.

Abstract

This entry discusses the history and describes the multitude of methods and applications of this important branch of stochastic process theory.

Keywords

Linear stochastic filtering; Markov step processes; Maximum likelihood estimation; Riccati equation; Stratonovich-Kushner equation

Estimation is the process of inferring the value of an unknown given quantity of interest from noisy, direct or indirect, observations of such a quantity. Due to its great practical relevance, estimation has a long history and an enormous variety of applications in all fields of engineering and science. A certainly incomplete list of possible application domains of estimation includes the following: statistics (Bard 1974; Ghosh et al. 1997; Koch 1999; Lehmann and Casella 1998; Tsybakov 2009; Wertz 1978), telecommunication systems (Sage and Melsa 1971; Schonhoff and Giordano 2006; Snyder 1968; Van Trees 1971), signal and image processing (Barkat 2005; Biemond et al. 1983; Elliott et al. 2008; Itakura 1971; Kay 1993; Kim and Woods 1998; Levy 2008; Najim 2008; Poor 1994; Tuncer and Friedlander 2009; Wakita 1973; Woods and Radewan 1977), aerospace engineering (McGee and Schmidt 1985), tracking (Bar-Shalom and Fortmann 1988; Bar-Shalom et al. 2001, 2013; Blackman and Popoli 1999; Farina and Studer 1985, 1986), navigation (Dissanayake et al. 2001; Durrant-Whyte and Bailey 2006a,b; Farrell and Barth 1999; Grewal et al. 2001; Mullane et al. 2011; Schmidt 1966; Smith et al. 1986; Thrun et al. 2006), control systems (Anderson and Moore 1979; Athans 1971; Goodwin et al. 2005; Joseph and Tou 1961; Kalman 1960a; Maybeck 1979, 1982; Söderström 1994; Stengel 1994), econometrics (Aoki 1987; Pindyck and Roberts 1974; Zellner 1971), geophysics (e.g., seismic deconvolution) (Bayless and Brigham 1970; Flinn et al. 1967; Mendel 1977, 1983, 1990), oceanography (Evensen 1994a; Ghil and Malanotte-Rizzoli 1991), weather forecasting (Evensen 1994b, 2007; McGarty 1971), environmental engineering (Dochain and Vanrolleghem 2001; Heemink and Segers 2002; Nachazel 1993), demographic systems (Leibungudt et al. 1983), automotive systems (Barbarisi et al. 2006; Stephant et al. 2004), failure detection (Chen and Patton 1999; Mangoubi 1998; Willsky 1976), power systems (Abur and Gómez Espósito 2004; Debs and Larson 1970; Miller and Lewis 1971; Monticelli 1999; Toyoda et al. 1970), nuclear engineering (Robinson 1963; Roman et al. 1971; Sage and Masters 1967; Venerus and Bullock 1970), biomedical engineering (Bekey 1973; Snyder 1970; Stark 1968), pattern recognition (Andrews 1972; Ho and Agrawala 1968; Lainiotis 1972), social networks (Snijders et al. 2012), etc.

Chapter Organization

The rest of the chapter is organized as follows. Section "Historical Overview on Estimation" will provide a historical overview on estimation. The next section will discuss applications of estimation. Connections between estimation and information theories will be explored in the subsequent section. Finally, the section "Conclusions and Future Trends" will conclude the chapter by discussing future trends in estimation. An extensive list of references is also provided.

Historical Overview on Estimation

A possibly incomplete, list of the major achievements on estimation theory and applications is reported in Table 1. The entries of the table, sorted in chronological order, provide for each contribution the name of the inventor (or inventors), the date, and a short description with main bibliographical references.

Probably the first important application of estimation dates back to the beginning of the nineteenth century whenever least-squares estimation (LSE), invented by Gauss in 1795 (Gauss 1995; Legendre 1810), was successfully exploited in astronomy for predicting planet orbits (Gauss 1806). Least-squares estimation follows a deterministic approach by minimizing the sum of squares of residuals defined as differences between observed data and model-predicted estimates. A subsequently introduced statistical approach is maximum likelihood estimation (MLE), popularized by R. A. Fisher between 1912 and 1922 (Fisher 1912, 1922, 1925). MLE consists of finding the estimate of the unknown quantity of interest as the value that maximizes the so-called likelihood function, defined as the conditional probability density function of the observed data given the quantity to be estimated. In intuitive terms, MLE maximizes the agreement of the estimate with the observed data. Whenever the observation noise is assumed Gaussian (Kim and Shevlyakov 2008; Park et al. 2013), MLE coincides with LSE.

While estimation problems had been addressed for several centuries, it was not until the 1940s that a systematic theory of estimation started to be established, mainly relying on the foundations of the modern theory of probability (Kolmogorov 1933). Actually, the roots of probability theory can be traced back to the calculus of combinatorics (the Stomachion puzzle invented by Archimedes (Netz and Noel 2011)) in the third century B.C. and to the gambling theory (work of Cardano, Pascal, de Fermat, Huygens) in the sixteenth–seventeenth centuries.

Differently from the previous work devoted to the estimation of constant parameters, in the period 1940–1960 the attention was mainly shifted toward the estimation of signals. In particular, Wiener in 1940 (Wiener 1949) and Kolmogorov in 1941 (Kolmogorov 1941) formulated and solved the problem of linear minimum mean-square error (MMSE) estimation of continuous-time and, respectively, discrete-time stationary random signals. In the late 1940s and in the 1950s, Wiener-Kolmogorov's theory was extended and generalized in many directions exploiting both time-domain and frequency-domain approaches. At the beginning of the 1960s Rudolf E. Kálmán made pioneering contributions to estimation by providing the mathematical foundations of the modern theory based on state-variable representations. In particular, Kálmán solved the linear MMSE filtering and prediction problems both in discrete-time (Kalman 1960b) and in continuous-time (Kalman and Bucy 1961); the resulting optimal estimator was named after him, Kalman filter (KF). As a further contribution, Kalman also singled out the key technical conditions, i.e., observability and controllability, for which the resulting optimal estimator turns out to be stable. Kalman's work went well beyond earlier contributions of A. Kolmogorov, N. Wiener, and their followers ("frequency-domain" approach) by means of a general state-space approach. From the theoretical viewpoint, the KF is an optimal estimator, in a wide sense, of the state of a linear dynamical system from noisy measurements; specifically it is the optimal MMSE estimator in

Estimation, Survey on, Table 1 Major developments on estimation

Archimedes	Third century B.C.	Combinatorics (Netz and Noel 2011) as the basis of probability
G. Cardano, B. Pascal, P. de Fermat, C. Huygens	Sixteenth–seventeenth centuries	Roots of the theory of probability (Devlin 2008)
J. F. Riccati	1722–1723	Differential Riccati equation (Riccati 1722, 1723), subsequently exploited in the theory of linear stochastic filtering

the Gaussian case (e.g., for normally distributed noises and initial state) and the best linear unbiased estimator irrespective of the noise and initial state distributions. From the practical viewpoint, the KF enjoys the desirable properties of being linear and acting recursively, step-by-step, on a noise-contaminated data stream. This allows for cheap real-time implementation on digital computers. Further, the universality of "state-variable representations" allows almost any estimation problem to be included in the KF framework. For these reasons, the KF is, and continues to be, an extremely effective and easy-to-implement tool for a great variety of practical tasks, e.g., to detect signals in noise or to estimate unmeasurable quantities from accessible observables. Due to the generality of the state estimation problem, which actually encompasses parameter and signal estimation as special cases, the literature on estimation since 1960 till today has been mostly concentrated on extensions and generalizations of Kalman's work in several directions. Considerable efforts, motivated by the ubiquitous presence of nonlinearities in practical estimation problems, have been devoted to nonlinear and/or non-Gaussian filtering, starting from the seminal papers of Stratonovich (1959, 1960) and Kushner (1962, 1967) for continuous-time systems, Ho and Lee (1964) for discrete-time systems, and Jazwinski (1966) for continuous-time systems with discrete-time observations. In these

papers, state estimation is cast in a probabilistic (Bayesian) framework as the problem of evolving in time the state conditional probability density given observations (Jazwinski 1970). Work on nonlinear filtering has produced over the years several nonlinear state estimation algorithms, e.g., the extended Kalman filter (EKF) (Schmidt 1966), the unscented Kalman filter (UKF) (Julier and Uhlmann 2004; Julier et al. 1995), the Gaussian-sum filter (Alspach and Sorenson 1972; Sorenson and Alspach 1970, 1971), the sequential Monte Carlo (also called particle) filter (SMCF) (Doucet et al. 2001; Gordon et al. 1993; Ristic et al. 2004), and the ensemble Kalman filter (EnKF) (Evensen 1994a,b, 2007) which have been, and are still now, successfully employed in various application domains. In particular, the SMCF and EnKF are stochastic simulation algorithms taking inspiration from the work in the 1940s on the Monte Carlo method (Metropolis and Ulam 1949) which has recently got renewed interest thanks to the tremendous advances in computing technology. A thorough review on nonlinear filtering can be found, e.g., in Daum (2005) and Crisan and Rozovskii (2011).

Other interesting areas of investigation have concerned smoothing (Bryson and Frazier 1963), robust filtering for systems subject to modeling uncertainties (Poor and Looze 1981), and state estimation for infinite-dimensional (i.e., distributed parameter and/or delay) systems (Balakrishnan and Lions 1967). Further, a lot of attention has been devoted to the implementation of the KF, specifically square-root filtering (Potter and Stern 1963) for improved numerical robustness and fast KF algorithms (Kailath 1973; Morf et al. 1974) for enhancing computational efficiency. Worth of mention is the work over the years on theoretical bounds on the estimation performance originated from the seminal papers of Rao (1945) and Cramér (1946) on the lower bound of the MSE for parameter estimation and subsequently extended in Tichavsky et al. (1998) to nonlinear filtering and in Hernandez et al. (2006) to more realistic estimation problems with possible missed and/or false measurements. An extensive review of this work on Bayesian bounds for estimation, nonlinear filtering, and tracking

can be found in van Trees and Bell (2007). A brief review of the earlier (until 1974) state of art in estimation can be found in Lainiotis (1974).

Applications

Astronomy

The problem of making estimates and predictions on the basis of noisy observations originally attracted the attention many centuries ago in the field of astronomy. In particular, the first attempt to provide an optimal estimate, i.e., such that a certain measure of the estimation error be minimized, was due to Galileo Galilei that, in his *Dialogue on the Two World Chief Systems* (1632) (Galilei 1632), suggested, as a possible criterion for estimating the position of Tycho Brahe's supernova, the estimate that required the "minimum amendments and smallest corrections" to the data. Later, C. F. Gauss mathematically specified this criterion by introducing in 1795 the least-squares method (Gauss 1806, 1995; Legendre 1810) which was successfully applied in 1801 to predict the location of the asteroid Ceres. This asteroid, originally discovered by the Italian astronomer Giuseppe Piazzi on January 1, 1801, and then lost in the glare of the sun, was in fact recovered 1 year later by the Hungarian astronomer F. X. von Zach exploiting the least-squares predictions of Ceres' position provided by Gauss.

Statistics

Starting from the work of Fisher in the 1920s (Fisher 1912, 1922, 1925), maximum likelihood estimation has been extensively employed in statistics for estimating the parameters of statistical models (Bard 1974; Ghosh et al. 1997; Koch 1999; Lehmann and Casella 1998; Tsybakov 2009; Wertz 1978).

Telecommunications and Signal/Image Processing

Wiener-Kolmogorov's theory on signal estimation, developed in the period 1940–1960 and originally conceived by Wiener during the Second World War for predicting aircraft

trajectories in order to direct the antiaircraft fire, subsequently originated many applications in telecommunications and signal/image processing (Barkat 2005; Biemond et al. 1983; Elliott et al. 2008; Itakura 1971; Kay 1993; Kim and Woods 1998; Levy 2008; Najim 2008; Poor 1994; Tuncer and Friedlander 2009; Van Trees 1971; Wakita 1973; Woods and Radewan 1977). For instance, Wiener filters have been successfully applied to linear prediction, acoustic echo cancellation, signal restoration, and image/video de-noising. But it was the discovery of the Kalman filter in 1960 that revolutionized estimation by providing an effective and powerful tool for the solution of any, static or dynamic, stationary or adaptive, linear estimation problem. A recently conducted, and probably non-exhaustive, search has detected the presence of over 16,000 patents related to the "Kalman filter," spreading over all areas of engineering and over a period of more than 50 years. What is astonishing is that even nowadays, more than 50 years after its discovery, one can see the continuous appearance of lots of new patents and scientific papers presenting novel applications and/or novel extensions in many directions (e.g., to nonlinear filtering) of the KF. Since 1992 the number of patents registered every year and related to the KF follows an exponential law.

Space Navigation and Aerospace Applications

The first important application of the Kalman filter was in the NASA (*National Aeronautic and Space Administration*) space program. As reported in a NASA technical report (McGee and Schmidt 1985), Kalman presented his new ideas while visiting Stanley F. Schmidt at the NASA Ames Research Center in 1960, and this meeting stimulated the use of the KF during the Apollo program (in particular, in the guidance system of Saturn V during Apollo 11 flight to the Moon), and, furthermore, in the NASA Space Shuttle and in Navy submarines and unmanned aerospace vehicles and weapons, such as cruise missiles. Further, to cope with the nonlinearity of the space navigation problem and the small word length of the onboard computer, the extended Kalman

filter for nonlinear systems and square-root filter implementations for enhanced numerical robustness have been developed as part of the NASA's Apollo program. The aerospace field was only the first of a long and continuously expanding list of application domains where the Kalman filter and its nonlinear generalizations have found widespread and beneficial use.

Control Systems and System Identification

The work on Kalman filtering (Kalman 1960b; Kalman and Bucy 1961) had also a significant impact on control system design and implementation. In Kalman (1960a) duality between estimation and control was pointed out, in that for a certain class of control and estimation problems one can solve the control (estimation) problem for a given dynamical system by resorting to a corresponding estimation (control) problem for a suitably defined dual system. In particular, the Kalman filter has been shown to be dual of the linear-quadratic (LQ) regulator, and the two dual techniques constitute the linear-quadratic-Gaussian (LQG) (Joseph and Tou 1961) regulator. The latter consists of an LQ regulator feeding back in a linear way the state estimate provided by a Kalman filter, which can be independently designed in view of the separation principle. The KF as well as LSE and MLE techniques are also widely used in system identification (Ljung 1999; Söderström and Stoica 1989) for both parameter estimation and output prediction purposes.

Tracking

One of the major application areas for estimation is tracking (Bar-Shalom and Fortmann 1988; Bar-Shalom et al. 2001, 2013; Blackman and Popoli 1999; Farina and Studer 1985, 1986), i.e., the task of following the motion of moving objects (e.g., aircrafts, ships, ground vehicles, persons, animals) given noisy measurements of kinematic variables from remote sensors (e.g., radar, sonar, video cameras, wireless sensors, etc.). The development of the Wiener filter in the 1940s was actually motivated by radar tracking of aircraft for automatic control of antiaircraft guns. Such filters began to be used in the 1950s whenever

computers were integrated with radar systems, and then in the 1960s more advanced and better performing Kalman filters came into use. Still today it can be said that the Kalman filter and its nonlinear generalizations (e.g., EKF (Schmidt 1966), UKF (Julier and Uhlmann 2004), and particle filter (Gordon et al. 1993)) represent the workhorses of tracking and sensor fusion. Tracking, however, is usually much more complicated than a simple state estimation problem due to the presence of false measurements (clutter) and multiple objects in the surveillance region of interest, as well as for the uncertainty about the origin of measurements. This requires to use, besides filtering algorithms, smart techniques for object detection as well as for association between detected objects and measurements. The problem of joint target tracking and classification has also been formulated as a hybrid state estimation problem and addressed in a number of papers (see, e.g., Smeth and Ristic (2004) and the references therein).

Econometrics

State and parameter estimation have been widely used in econometrics (Aoki 1987) for analyzing and/or predicting financial time series (e.g., stock prices, interest rates, unemployment rates, volatility etc.).

Geophysics

Wiener and Kalman filtering techniques are employed in reflection seismology for estimating the unknown earth reflectivity function given noisy measurements of the seismic wavelet's echoes recorded by a geophone. This estimation problem, known as seismic deconvolution (Mendel 1977, 1983, 1990), has been successfully exploited, e.g., for oil exploration.

Data Assimilation for Weather Forecasting and Oceanography

Another interesting application of estimation theory is data assimilation (Ghil and Malanotte-Rizzoli 1991) which consists of incorporating noisy observations into a computer simulation model of a real system. Data assimilation has widespread use especially in weather forecasting and oceanography. A large-scale state-space model is typically obtained from the physical system model, expressed in terms of partial differential equations (PDEs), by means of a suitable spatial discretization technique so that data assimilation is cast into a state estimation problem. To deal with the huge dimensionality of the resulting state vector, appropriate filtering techniques with reduced computational load have been suitably developed (Evensen 2007).

Global Navigation Satellite Systems

Global Navigation Satellite Systems (GNSSs), such as GPS put into service in 1993 by the US Department of Defense, provide nowadays a commercially diffused technology exploited by millions of users all over the world for navigation purposes, wherein the Kalman filter plays a key role (Bar-Shalom et al. 2001). In fact, the Kalman filter not only is employed in the core of the GNSS to estimate the trajectories of all the satellites, the drifts and rates of all system clocks, and hundreds of parameters related to atmospheric propagation delay, but also any GNSS receiver uses a nonlinear Kalman filter, e.g., EKF, in order to estimate its own position and velocity along with the bias and drift of its own clock with respect to the GNSS time.

Robotic Navigation (SLAM)

Recursive state estimation is commonly employed in mobile robotics (Thrun et al. 2006) in order to on-line estimate the robot pose, location and velocity, and, sometimes, also the location and features of the surrounding objects in the environment exploiting measurements provided by onboard sensors; the overall joint estimation problem is referred to as SLAM (simultaneous localization and mapping) (Dissanayake et al. 2001; Durrant-Whyte and Bailey 2006a,b; Mullane et al. 2011; Smith et al. 1986; Thrun et al. 2006).

Automotive Systems

Several automotive applications of the Kalman filter, or of its nonlinear variants, are reported in the literature for the estimation of various

quantities of interest that cannot be directly measured, e.g., roll angle, sideslip angle, road-tire forces, heading direction, vehicle mass, state of charge of the battery (Barbarisi et al. 2006), etc. In general, one of the major applications of state estimation is the development of virtual sensors, i.e., estimation algorithms for physical variables of interest, that cannot be directly measured for technical and/or economic reasons (Stephant et al. 2004).

Miscellaneous Applications

Other areas where estimation has found numerous applications include electric power systems (Abur and Gómez Espósito 2004; Debs and Larson 1970; Miller and Lewis 1971; Monticelli 1999; Toyoda et al. 1970), nuclear reactors (Robinson 1963; Roman et al. 1971; Sage and Masters 1967; Venerus and Bullock 1970), biomedical engineering (Bekey 1973; Snyder 1970; Stark 1968), pattern recognition (Andrews 1972; Ho and Agrawala 1968; Lainiotis 1972), and many others.

Connection Between Information and Estimation Theories

In this section, the link between two fundamental quantities in information theory and estimation theory, i.e., the mutual information (MI) and respectively the minimum mean-square error (MMSE), is investigated. In particular, a strikingly simple but very general relationship can be established between the MI of the input and the output of an additive Gaussian channel and the MMSE in estimating the input given the output, regardless of the input distribution (Guo et al. 2005). Although this functional relation holds for general settings of the Gaussian channel (e.g., both discrete-time and continuous-time, possibly vector, channels), in order to avoid the heavy mathematical preliminaries needed to treat rigorously the general problem, two simple scalar cases, a static and a (continuous-time) dynamic one, will be discussed just to highlight the main concept.

Static Scalar Case

Consider two scalar real-valued random variables, x and y, related by

$$y = \sqrt{\sigma}x + v \qquad (1)$$

where v, the measurement noise, is a standard Gaussian random variable independent of x and σ can be regarded as the gain in the output signal-to-noise ratio (SNR) due to the channel. By considering the MI between x and y as a function of σ, i.e., $I(\sigma) = I\left(x, \sqrt{\sigma}x + v\right)$, it can be shown that the following relation holds (Guo et al. 2005):

$$\frac{d}{d\sigma}I(\sigma) = \frac{1}{2}\,E\left[(x - \hat{x}(\sigma))^2\right] \qquad (2)$$

where $\hat{x}(\sigma) = E\left[x|\sqrt{\sigma}x + v\right]$ is the minimum mean-square error estimate of x given y. Figure 1 displays the behavior of both MI, in natural logarithmic units of information (nats), and MMSE versus SNR.

As mentioned in Guo et al. (2005), the above information-estimation relationship (2) has found a number of applications, e.g., in nonlinear filtering, in multiuser detection, in power allocation over parallel Gaussian channels, in the proof of Shannon's entropy power inequality and its generalizations, as well as in the treatment of the capacity region of several multiuser channels.

Linear Dynamic Continuous-Time Case

While in the static case the MI is assumed to be a function of the SNR, in the dynamic case it is of great interest to investigate the relationship between the MI and the MMSE as a function of time.

Consider the following first-order (scalar) linear Gaussian continuous-time stochastic dynamical system:

$$\begin{aligned} dx_t &= ax_t dt + dw_t \\ dy_t &= \sqrt{\sigma}x_t\, dt + dv_t \end{aligned} \qquad (3)$$

where a is a real-valued constant while w_t and v_t are independent standard Brownian motion processes that represent the process and,

E
Estimation, Survey on, Fig. 1 MI and MMSE versus SNR

respectively, measurement noises. Defining by $x_0^t \triangleq \{x_s, 0 \leq s \leq t\}$ the collection of all states up to time t and analogously $y_0^t \triangleq \{y_s, 0 \leq s \leq t\}$ for the channel outputs (i.e., measurements) and considering the MI between x_0^t and y_0^t as a function of time t, i.e., $I(t) = I\left(x_0^t, y_0^t\right)$, it can be shown that (Duncan 1970; Mayer-Wolf and Zakai 1983)

$$\frac{d}{dt} I(t) = \frac{\sigma}{2} E\left[(x_t - \hat{x}_t)^2\right] \qquad (4)$$

where $\hat{x}_t = E\left[x_t | y_0^t\right]$ is the minimum mean-square error estimate of the state x_t given all the channel outputs up to time t, i.e., y_0^t. Figure 2 depicts the time behavior of both MI and MMSE for several values of σ and $a = 1$.

Conclusions and Future Trends

Despite the long history of estimation and the huge amount of work on several theoretical and practical aspects of estimation, there is still a lot of research investigation to be done in several directions. Among the many new future trends, networked estimation and quantum estimation (briefly overviewed in the subsequent parts of this section) certainly deserve special attention due to the growing interest on wireless sensor networks and, respectively, quantum computing.

Networked Information Fusion and Estimation

Information or data fusion is about combining, or fusing, information or data from multiple sources to provide knowledge that is not evident from a single source (Bar-Shalom et al. 2013; Farina and Studer 1986). In 1986, an effort to standardize the terminology related to data fusion began and the JDL (Joint Directors of Laboratories) data fusion working group was established. The result of that effort was the conception of a process model for data fusion and a data fusion lexicon (Blasch et al. 2012; Hall and Llinas 1997). Information and data fusion are mainly supported by sensor networks which present the following advantages over a single sensor:
Estimation, Survey on, Fig. 2 MI and MMSE for different values of σ (-10 dB, 0 dB, $+10$ dB) and $a = 1$

- Can be deployed over wide regions
- Provide diverse characteristics/viewing angles of the observed phenomenon
- Are more robust to failures
- Gather more data that, once fused, provide a more complete picture of the observed phenomenon
- Allow better geographical coverage, i.e., wider area and less terrain obstructions.

Sensor network architectures can be centralized, hierarchical (with or without feedback), and distributed (peer-to-peer). Today's trend for many monitoring and decision-making tasks is to exploit large-scale networks of low-cost and low-energy consumption devices with sensing, communication, and processing capabilities. For scalability issues, such networks should operate in a fully distributed (peer-to-peer) fashion, i.e., with no centralized coordination, so as to achieve in each node a global estimation/decision objective through localized processing only.

The attainment of this goal actually requires several issues to be addressed like:

- Spatial and temporal sensor alignment
- Scalable fusion
- Robustness with respect to data incest (or double counting), i.e., repeated use of the same information
- Handling data latency (e.g., out-of-sequence measurements/estimates)
- Communication bandwidth limitations

In particular, to counteract data incest the so-called *covariance intersection* (Julier and Uhlmann 1997) robust fusion approach has been proposed to guarantee, at the price of some conservatism, consistency of the fused estimate when combining estimates from different nodes with unknown correlations. For scalable fusion, a consensus approach (Olfati-Saber et al. 2007) can be undertaken. This allows to carry out a global (i.e., over the whole network) processing task by iterating local processing steps among neighboring nodes.

Several consensus algorithms have been proposed for distributed parameter (Calafiore and Abrate 2009) or state (Alriksson and

Rantzer 2006; Kamgarpour and Tomlin 2007; Olfati-Saber 2007; Stankovic et al. 2009; Xiao et al. 2005) estimation. Recently, Battistelli and Chisci (2014) introduced a generalized consensus on probability densities which opens up the possibility to perform in a fully distributed and scalable way any Bayesian estimation task over a sensor network. As by-products, this approach allowed to derive consensus Kalman filters with guaranteed stability under minimal requirements of system observability and network connectivity (Battistelli et al. 2011, 2012; Battistelli and Chisci 2014), consensus nonlinear filters (Battistelli et al. 2012), and a consensus CPHD filter for distributed multitarget tracking (Battistelli et al. 2013). Despite these interesting preliminary results, networked estimation is still a very active research area with many open problems related to energy efficiency, estimation performance optimality, robustness with respect to delays and/or data losses, etc.

Quantum Estimation

Quantum estimation theory consists of a generalization of the classical estimation theory in terms of quantum mechanics. As a matter of fact, the statistical theory can be seen as a particular case of the more general quantum theory (Helstrom 1969, 1976). Quantum mechanics presents practical applications in several fields of technology (Personick 1971) such as, the use of quantum number generators in place of the classical random number generators. Moreover, manipulating the energy states of the cesium atoms, it is possible to suppress the quantum noise levels and consequently improve the accuracy of atomic clocks. Quantum mechanics can also be exploited to solve optimization problems, giving sometimes optimization algorithms that are faster than conventional ones. For instance, McGeoch and Wang (2013) provided an experimental study of algorithms based on quantum annealing. Interestingly, the results of McGeoch and Wang (2013) have shown that this approach allows to obtain better solutions with respect to those found with conventional software solvers. In quantum mechanics, also the Kalman filter has found its proper form, as the quantum Kalman filter.

In Iida et al. (2010) the quantum Kalman filter is applied to an optical cavity composed of mirrors and crystals inside, which interacts with a probe laser. In particular, a form of a quantum stochastic differential equation can be written for such a system so as to design the algorithm that updates the estimates of the system variables on the basis of the measurement outcome of the system.

Abstract

Recent developments in computer and communication technologies have led to a new type of large-scale resource-constrained wireless

embedded control systems. It is desirable in these systems to limit the sensor and control computation and/or communication to instances when the system needs attention. However, classical sampled-data control is based on performing sensing and actuation periodically rather than when the system needs attention. This article discusses event- and self-triggered control systems where sensing and actuation is performed when needed. Event-triggered control is reactive and generates sensor sampling and control actuation when, for instance, the plant state deviates more than a certain threshold from a desired value. Self-triggered control, on the other hand, is proactive and computes the next sampling or actuation instance ahead of time. The basics of these control strategies are introduced together with references for further reading.

Keywords

Event-triggered control; Hybrid systems; Real-time control; Resource-constrained embedded control; Sampled-data systems; Self-triggered control

Introduction

In standard control textbooks, e.g., Aström and Wittenmark (1997) and Franklin et al. (2010), periodic control is presented as the only choice for implementing feedback control laws on digital platforms. Although this time-triggered control paradigm has proven to be extremely successful in many digital control applications, recent developments in computer and communication technologies have led to a new type of large-scale resource-constrained (wireless) control systems that call for a reconsideration of this traditional paradigm. In particular, the increasing popularity of (shared) wired and wireless networked control systems raises the importance of explicitly addressing energy, computation, and communication constraints when designing feedback control loops. Aperiodic control strategies that allow the inter-execution times of control tasks to be varying in time offer potential advantages with

respect to periodic control when handling these constraints, but they also introduce many new interesting theoretical and practical challenges.

Although the discussions regarding periodic vs. aperiodic implementation of feedback control loops date back to the beginning of computer-controlled systems, e.g., Gupta (1963), in the late 1990s two influential papers (Årzén 1999; Åström and Bernhardsson 1999) highlighted the advantages of *event-based* feedback control. These two papers spurred the development of the first *systematic designs* of event-based implementations of stabilizing feedback control laws, e.g., Yook et al. (2002), Tabuada (2007), Heemels et al. (2008), and Henningsson et al. (2008). Since then, several researchers have improved and generalized these results and alternative approaches have appeared. In the meantime, also so-called *self-triggered* control (Velasco et al. 2003) emerged. Event-triggered and self-triggered control systems consist of two elements, namely, a feedback controller that computes the control input and a triggering mechanism that determines when the control input has to be updated again. The difference between event-triggered control and self-triggered control is that the former is reactive, while the latter is proactive. Indeed, in event-triggered control, a triggering condition based on current measurements is continuously monitored and when the condition holds, an event is triggered. In self-triggered control the next update time is precomputed at a control update time based on predictions using previously received data and knowledge of the plant dynamics. In some cases, it is advantageous to combine event-triggered and self-triggered control resulting in a control system reactive to unpredictable disturbances and proactive by predicting future use of resources.

Time-Triggered, Event-Triggered and Self-Triggered Control

To indicate the differences between various digital implementations of feedback control laws, consider the control of the nonlinear plant

$$\dot{x} = f(x, u) \qquad (1)$$

with $x \in \mathbb{R}^{n_x}$ the state variable and $u \in \mathbb{R}^{n_u}$ the input variable. The system is controlled by a nonlinear state feedback law

$$u = h(x) \qquad (2)$$

where $h : \mathbb{R}^{n_x} \to \mathbb{R}^{n_u}$ is an appropriate mapping that has to be implemented on a digital platform. Recomputing the control value and updating the actuator signals will occur at times denoted by $t_0, t_1, t_2, \dots$ with $t_0 = 0$. If we assume the inputs to be held constant in between the successive recomputations of the control law (referred to as sample-and-hold or zero-order-hold), we have

$$u(t) = u(t_k) = h(x(t_k)) \quad \forall t \in [t_k, t_{k+1}), \ k \in \mathbb{N}. \qquad (3)$$

We refer to the instants $\{t_k\}_{k \in \mathbb{N}}$ as the *triggering* times or *execution* times. Based on these times we can easily explain the difference between time-triggered control, event-triggered control, and self-triggered control.

In *time-triggered* control we have the equality $t_k = kT_s$ with $T_s > 0$ being the sampling period. Hence, the updates take place equidistantly in time irrespective of how the system behaves. There is no "feedback mechanism" in determining the execution times; they are determined a priori and in "open loop." Another way of writing the triggering mechanism in time-triggered control is

$$t_{k+1} = t_k + T_s, \ k \in \mathbb{N} \qquad (4)$$

with $t_0 = 0$.

In *event-triggered* control the next execution time of the controller is determined by an event-triggering mechanism that continuously verifies if a certain condition based on the actual state variable becomes true. This condition includes often also information on the state variable $x(t_k)$ at the previous execution time t_k and can be written, for instance, as $C(x(t), x(t_k)) > 0$. Formally, the execution times are then determined by

$$t_{k+1} = \inf\{t > t_k \mid C(x(t), x(t_k)) > 0\} \qquad (5)$$

with $t_0 = 0$. Hence, it is clear from (5) that there is a *feedback* mechanism present in the determination of the next execution time as it is based on the measured state variable. In this sense event-triggered control is *reactive*.

Finally, in *self-triggered* control the next execution time is determined *proactively* based on the measured state $x(t_k)$ at the previous execution time. In particular, there is a function $M : \mathbb{R}^{n_x} \to \mathbb{R}_{\geq 0}$ that specifies the next execution time as

$$t_{k+1} = t_k + M(x(t_k)) \qquad (6)$$

with $t_0 = 0$. As a consequence, in self-triggered control both the control value $u(t_k)$ and the next execution time t_{k+1} are computed at execution time t_k. In between t_k and t_{k+1}, no further actions are required from the controller. Note that the time-triggered implementation can be seen as a special case of the self-triggered implementation by taking $M(x) = T_s$ for all $x \in \mathbb{R}^{n_x}$.

Clearly, in all the three implementation schemes T_s, C and M are chosen together with the feedback law given through h to provide stability and performance guarantees and to realize a certain utilization of computer and communication resources.

Lyapunov-Based Analysis

Much work on event-triggered control used one of the following two modeling and analysis frameworks: The perturbation approach and the hybrid system approach.

Perturbation Approach

In the perturbation approach one adopts perturbed models that describe how the event-triggered implementation of the control law perturbs the ideal continuous-time implementation $u(t) = h(x(t))$, $t \in \mathbb{R}_{\geq 0}$. In order to do so, consider the error e given by

$$e(t) = x(t_k) - x(t) \ \text{for } t \in [t_k, t_{k+1}), \ k \in \mathbb{N}. \qquad (7)$$

Using this error variable we can write the closed-loop system based on (1) and (3) as

$$\dot{x} = f(x, h(x + e)). \qquad (8)$$

Essentially, the three implementations discussed above have their own way of indicating when an execution takes place and the error e is reset to zero. The equation (8) clearly shows how the ideal closed-loop system is *perturbed* by using a time-triggered, event-triggered, or self-triggered implementation of the feedback law in (2). Indeed, when $e = 0$ we obtain the ideal closed loop

$$\dot{x} = f(x, h(x)). \qquad (9)$$

The control law in (2) is typically chosen so as to guarantee that the system in (9) has certain global asymptotic stability (GAS) properties. In particular, it is often assumed that there exists a Lyapunov function $V : \mathbb{R}_{n_x} \to \mathbb{R}_{\geq 0}$ in the sense that V is positive definite and for all $x \in \mathbb{R}^{n_x}$ we have

$$\frac{\partial V}{\partial x} f(x, h(x)) \leq -\|x\|^2. \qquad (10)$$

Note that this inequality is stronger than strictly needed (at least for nonlinear systems), but for pedagogical reasons we choose this simpler formulation. For the perturbed model, the inequality in (10) can in certain cases (including linear systems) be modified to

$$\frac{\partial V}{\partial x} f(x, h(x)) \leq -\|x\|^2 + \beta \|e\|^2 \qquad (11)$$

in which $\beta > 0$ is a constant used to indicate how the presence of the implementation error e affects the decrease of the Lyapunov function. Based on (10) one can now choose the function C in (5) to preserve GAS of the event-triggered implementation. For instance, $C(x(t), x(t_k)) = \|x(t_k) - x(t)\| - \sigma \|x(t)\|$, i.e.,

$$t_{k+1} = \inf\{t > t_k \mid \|e(t)\| > \sigma \|x(t)\|\}, \qquad (12)$$

assures that

$$\|e\| \leq \sigma \|x\| \qquad (13)$$

holds. When $\sigma < 1/\beta$, we obtain from (11) and (13) that GAS properties are preserved for the event-triggered implementation. Besides, under certain conditions provided in Tabuada (2007), a global positive lower bound exists on the inter-execution times, i.e., there exists a $\tau_{\min} > 0$ such that $t_{k+1} - t_k > \tau_{\min}$ for all $k \in \mathbb{N}$ and all initial states x_0.

Also self-triggered controllers can be derived using the perturbation approach. In this case, stability properties can be guaranteed by choosing M in (6) ensuring that $C(x(t), x(t_k)) \leq 0$ holds for all times $t \in [t_k, t_{k+1})$ and all $k \in \mathbb{N}$.

Hybrid System Approach

By taking as a state variable $\xi = (x, e)$, one can write the closed-loop event-triggered control system given by (1), (3), and (5) as the hybrid impulsive system (Goebel et al. 2009)

$$\dot{\xi} = \begin{pmatrix} f(x, h(x + e)) \\ -f(x, h(x + e)) \end{pmatrix} \text{ when } C(x, x + e) \geq 0 \qquad (14a)$$

$$\xi^+ = \begin{pmatrix} x \\ 0 \end{pmatrix} \text{ when } C(x, x + e) \leq 0. \qquad (14b)$$

This observation was made in Donkers and Heemels (2010, 2012) and Postoyan et al. (2011). Tools from hybrid system theory can be used to analyze this model, which is more accurate as it includes the error dynamics of the event-triggered closed-loop system. In fact, the stability bounds obtained via the hybrid system approach can be proven to be never worse than ones obtained using the perturbation approach in many cases, see, e.g., Donkers and Heemels (2012), and typically the hybrid system approach provides (strictly) better results in practice. However, in general an analysis via the hybrid system approach is more complicated than using a perturbation approach.

Note that by including a time variable τ, one can also write the closed-loop system corresponding to self-triggered control (1), (3), and (6) as a hybrid system using the state variable $\chi = (x, e, \tau)$. This leads to the model

E

$$\dot{\chi} = \begin{pmatrix} f(x, h(x+e)) \\ -f(x, h(x+e)) \\ 1 \end{pmatrix} \text{when} 0 \leq \tau \leq M(x+e)$$

$$(15a)$$

$$\chi^+ = \begin{pmatrix} x \\ 0 \\ 0 \end{pmatrix} \text{ when } \tau = M(x+e), \qquad (15b)$$

which can be used for analysis based on hybrid tools as well.

Alternative Event-Triggering Mechanisms

There are various alternative event-triggering mechanisms. A few of them are described in this section.

Relative, Absolute, and Mixed Triggering Conditions

Above we discussed a very basic event-triggering condition in the form given in (12), which is sometimes called *relative* triggering as the next control task is executed at the instant when the ratio of the norms of the error $\|e\|$ and the measured state $\|x\|$ is larger than or equal to σ. Also *absolute* triggering of the form

$$t_{k+1} = \inf\{t > t_k \mid \|e(t)\| \geq \delta\} \qquad (16)$$

can be considered. Here $\delta > 0$ is an absolute threshold, which has given this scheme the name send-on-delta (Miskowicz 2006). Recently, a *mixed* triggering mechanism of the form

$$t_{k+1} = \inf\{t > t_k \mid \|e(t)\| \geq \sigma\|x(t)\| + \delta\},$$

$$(17)$$

combining an absolute and a relative threshold, was proposed (Donkers and Heemels 2012). It is particularly effective in the context of output-based control.

Model-Based Triggering

In the triggering conditions discussed so far, essentially the current control value $u(t)$ is based on a *held* value $x(t_k)$ of the state variable, as specified in (3). However, if good model-based information regarding the plant is available, one can use better model-based predictions of the actuator signal. For instance, in the linear context, (Lunze and Lehmann 2010) proposed to use a *control input generator* instead of a plain zero-order hold function. In fact, the plant model was described by

$$\dot{x} = Ax + Bu + Ew \qquad (18)$$

with $x \in \mathbb{R}^{n_x}$ the state variable, $u \in \mathbb{R}^{n_u}$ the input variable, and $w \in \mathbb{R}^{n_w}$ a bounded disturbance input. It was assumed that a well functioning state feedback controller $u = Kx$ was available. The control input generator was then based on the model-based predictions given for $[t_k, t_{k+1})$ by

$$\dot{x}_s(t) = (A + BK)x_s(t) + E\hat{w}(t_k)$$

$$\text{with } x_s(t_k) = x(t_k) \qquad (19)$$

and $\hat{w}(t_k)$ is an estimate for the (average) disturbance value, which is determined at execution time t_k, $k \in \mathbb{N}$. The applied input to the actuator is then given by $u(t) = Kx_s(t)$ for $t \in [t_k, t_{k+1})$, $k \in \mathbb{N}$. Note that (19) provides a prediction of the closed-loop state evolution using the latest received value of the state $x(t_k)$ and the estimate $\hat{w}(t_k)$ of the disturbances. Also the event-triggering condition is based on this model-based prediction of the state as it is given by

$$t_{k+1} = \inf\{t > t_k \mid \|x_s(t) - x(t)\| \geq \delta\}. \quad (20)$$

Hence, when the prediction $x_s(t)$ diverts to far from the measured state $x(t)$, the next event is triggered so that updates of the state are sent to the actuator. These model-based triggering schemes can enhance the communication savings as they reduce the number of events by using model-based knowledge.

Other model-based event-triggered control schemes are proposed, for instance, in Yook et al. (2002), Garcia and Antsaklis (2013), and Heemels and Donkers (2013).

Triggering with Time-Regularization

Time-regularization was proposed for *output-based* triggering to avoid the occurrence of accumulations in the execution times (Zeno behavior) that would obstruct the existence of a positive lower bound on the inter-execution times $t_{k+1} - t_k$, $k \in \mathbb{N}$. In Tallapragada and Chopra (2012a,b), the triggering update

$$t_{k+1} = \inf\{t > t_k + T \mid \|e(t)\| \geq \sigma\|x(t)\|\} \tag{21}$$

was proposed, where $T > 0$ is a built-in lower bound on the minimal inter-execution times. The authors discussed how T and σ can be designed to guarantee closed-loop stability. In Heemels et al. (2008) a similar triggering was proposed using an absolute-type of triggering.

An alternative to exploiting a built-in lower bound T is combining ideas from time-triggered control and event-triggering control. Essentially, the idea is to only verify a specific event-triggering condition at certain equidistant time instants kT_s, $k \in \mathbb{N}$, where $T_s > 0$ is the sampling period. Such proposals were mentioned in, for instance, Årzén (1999), Yook et al. (2002), Henningsson et al. (2008), and Heemels et al. (2008, 2013). In this case the execution times are given by

$$t_{k+1} = \inf\{t > t_k \mid t = kT_s, \ k \in \mathbb{N},$$
$$\text{and } \|e(t)\| \geq \sigma\|x(t)\|\} \tag{22}$$

in case a relative triggering is used. In Heemels et al. (2013) the term *periodic event-triggered control* was coined for this type of control.

Decentralized Triggering Conditions

Another important extension of the mentioned event-triggered controllers, especially in large-scale networked systems, is the decentralization of the event-triggered control. Indeed, if one focuses on any of the abovementioned event-triggering conditions (take, e.g., (5)), it is obvious that the full state variable $x(t)$ has to be continuously available in a central coordinator to determine if an event is triggered or not. If the sensors that measure the state are physically distributed over a wide area, this assumption is prohibitive for its implementation. In such cases, it is of high practical importance that the event-triggering mechanism can be decentralized and the execution of control tasks can be executed based on local information. One first idea could be to use *local* event-triggering mechanisms for the i-th sensor that measures x_i. One could "decentralize" the condition (5), into

$$t_{k^i+1}^i = \inf\{t > t_{k^i}^i \mid \|e_i(t)\| \geq \sigma\|x_i(t)\|\}, \tag{23}$$

in which $e_i(t) = x_i(t_{k^i}^i) - x_i(t)$ for $t \in [t_{k^i}^i, t_{k^i+1}^i)$, $k^i \in \mathbb{N}$. Note that each sensor now has its own execution times $t_{k^i}^i$, $k^i \in \mathbb{N}$ at which the information $x_i(t)$ is transmitted. More importantly, the triggering condition (23) is based on local data only and does not need a central coordinator having access to the complete state information. Besides since (23) still guarantees that (13) holds, stability properties can still be guaranteed; see Mazo and Tabuada (2011).

Several other proposals for decentralized event-triggered control schemes were made, e.g., Persis et al. (2013), Wang and Lemmon (2011), Garcia and Antsaklis (2013), Yook et al. (2002), and Donkers and Heemels (2012).

Triggering for Multi-agent Systems

Event-triggered control strategies are suitable for cooperative control of multi-agent systems. In multi-agent systems, local control actions of individual agents should lead to a desirable global behavior of the overall system. A prototype problem for control of multi-agent systems is the agreement problem (also called the consensus or rendezvous problem), where the states of all agents should converge to a common value (sometimes the average of the agents' initial conditions). The agreement problem has been shown to be solvable for certain low-order dynamical agents in both continuous and discrete time, e.g., Olfati-Saber et al. (2007). It was recently shown in Dimarogonas et al. (2012), Shi and Johansson (2011), and Seyboth et al. (2013) that the agreement problem can be solved using event-triggered control. In Seyboth et al. (2013)

the triggering times for agent i are determined by

$$t^i_{k^i+1} = \inf\{t > t^i_{k^i} \mid C_i(x_i(t), x_i(t^i_{k^i})) > 0\}, \tag{24}$$

which should be compared to the triggering times as specified through (5). The triggering condition compares the current state value with the one previously communicated, similarly to the previously discussed decentralized event-triggered control (see (23)), but now the communication is *only* to the agent's neighbors. Using such event-triggered communication, the convergence rate to agreement (i.e., $\|x_i(t) - x_j(t)\| \rightarrow 0$ as $t \rightarrow \infty$ for all i, j) can be maintained with a much lower communication rate than for time-triggered communication.

Outlook

Many simulation and experimental results show that event-triggered and self-triggered control strategies are capable of reducing the number of control task executions, while retaining a satisfactory closed-loop performance. In spite of these results, the actual deployment of these novel control paradigms in relevant applications is still rather marginal. Some exceptions include recent event-triggered control applications in underwater vehicles (Teixeira et al. 2010), process control (Lehmann et al. 2012), and control over wireless networks (Araujo et al. 2014). To foster the further development of event-triggered and self-triggered controllers in the future, it is therefore important to validate these strategies in practice, next to building up a complete system theory for them. Regarding the latter, it is fair to say that, even though many interesting results are currently available, the system theory for event-triggered and self-triggered control is far from being mature, certainly compared to the vast literature on time-triggered (periodic) sampled-data control. As such, many theoretical and practical challenges are ahead of us in this appealing research field.

Evolutionary Games

Eitan Altman
INRIA, Sophia-Antipolis, France

Abstract

Evolutionary games constitute the most recent major mathematical tool for understanding, modelling and predicting evolution in biology and other fields. They complement other well establlished tools such as branching processes and the Lotka-Volterra (1910) equations (e.g. for the predator - prey dynamics or for epidemics evolution). Evolutionary Games also brings novel features to game theory. First, it focuses on the dynamics of competition rather than restricting attention to the equilibrium. In particular, it tries to explain how an equilibrium emerges. Second, it brings new definitions of stability, that are more adapted to the context of large populations. Finally, in contrast to standard game theory, players are not assumed to be "rational" or "knowledgeable" as to anticipate the other players' choices. The objective of this article, is to present foundations as well as recent advances in evolutionary games, highlight the novel concepts that they introduce with respect

to game theory as formulated by John Nash, and describe through several examples their huge potential as tools for modeling interactions in complex systems.

Keywords

Evolutionary stable strategies; Fitness; Replicator dynamics

Introduction

Evolutionary game theory is the youngest of several mathematical tools used in describing and modeling evolution. It was preceded by the theory of branching processes (Watson and Francis Galton 1875) and its extensions (Altman 2008) which have been introduced in order to explain the evolution of family names in the English population of the second half of the nineteenth century. This theory makes use of the probabilistic distribution of the number of offspring of an individual in order to predict the probability at which the whole population would become eventually extinct. It describes the evolution of the number of offsprings of a given individual. The Lotka-Volterra equations (Lotka-Volterra 1910) and their extensions are differential equations that describe the population size of each of several species that have a predator-prey type relation. One of the foundations in evolutionary games (and its extension to population games) which is often used as the starting point in their definition is the replicator dynamics which, similarly to the Lotka-Volterra equations, describe the evolution of the size of various species that interact with each other (or of various behaviors within a given population). In both the Lotka-Volterra equations and in replicator dynamics, the evolution of the size of one type of population may depend on the sizes of all other populations. Yet, unlike the Lotka-Volterra equations, the object of the modeling is the normalized sizes of populations rather than the size itself. By normalized size of some type, we mean the fraction of that type within the whole population. A basic feature in

evolutionary games is, thus, that the evolution of the fraction of a given type in the population depends on the sizes of other types only through the normalized size rather than through their actual one.

The relative rate of the decrease or increase of the normalized population size of some type in the replicator dynamics is what we call fitness and is to be understood in the Darwinian sense. If some type or some behavior increases more than another one, then it has a larger fitness. the evolution of the fitness as described by the replicator dynamics is a central object of study in evolutionary games.

So far we did not actually consider any game and just discussed ways of modeling evolution. The relation to game theory is due to the fact that under some conditions, the fitness converges to some fixed limit, which can be identified as an equilibrium of a matrix game in which the utilities of the players are the fitnesses. This limit is then called an ESS – evolutionary stable strategy – as defined by Meynard Smith and Price in Maynard Smith and Price (1973). It can be computed using elementary tools in matrix games and then used for predicting the (long term) distribution of behaviors within a population. Note that an equilibrium in a matrix game can be obtained only when the players of the matrix game are rational (each one maximizing its expected utility, being aware of the utilities of other players and of the fact that these players maximize their utilities, etc.). A central contribution of evolutionary games is thus to show that evolution of possibly nonrational populations converges under some conditions to the equilibrium of a game played by rational players. This surprising relationship between the equilibrium of a noncooperative matrix game and the limit points of the fitness dynamics has been supported by a rich body of experimental results; see Friedman (1996).

On the importance of the ESS for understanding the evolution of species, Dawkins writes in his book "The Selfish Gene" (Dawkins 1976): "we may come to look back on the invention of the ESS concept as one of the most important

advances in evolutionary theory since Darwin." He further specifies: "Maynard Smith's concept of the ESS will enable us, for the first time, to see clearly how a collection of independent selfish entities can come to resemble a single organized whole."

Here we shall follow the nontraditional approach describing evolutionary games: we shall first introduce the replicator dynamics and then introduce the game theoretic interpretation related to it.

Replicator Dynamics

In the biological context, the replicator dynamics is a differential equation that describes the way in which the usage of strategies changes in time. They are based on the idea that the average growth rate per individual that uses a given strategy is proportional to the excess of fitness of that strategy with respect to the average fitness.

In engineering, the replicator dynamics could be viewed as a rule for updating mixed strategies by individuals. It is a decentralized rule since it only requires knowing the average utility of the population rather than the strategy of each individual.

Replicator dynamics is one of the most studied dynamics in evolutionary game theory. It has been introduced by Taylor and Jonker (1978). The replicator dynamics has been used for describing the evolution of road traffic congestion in which the fitness is determined by the strategies chosen by all drivers (Sandholm 2009). It has also been studied in the context of the association problem in wireless communications (Shakkottai et al. 2007).

Consider a set of N strategies and let $p_j(t)$ be the fraction of the whole population that uses strategy j at time t. Let $p(t)$ be the corresponding N-dimensional vector. A function f_j is associated with the growth rate of strategy j, and it is assumed to depend on the fraction of each of the N strategies in the population. There are various forms of replicator dynamics (Sandholm 2009) and we describe here the one most commonly used. It is given by

$$\dot{p}_j(t) = \mu\, p_j(t) \left[f_j(p(t)) - \sum_{k=1}^{N} p_k(t) f_k(p(t)) \right],$$
(1)

where μ is some positive constant and the payoff function f_k is called the fitness of strategy k.

In evolutionary games, evolution is assumed to be due to pairwise interactions between players, as will be described in the next section. Therefore, f_k has the form $f_k(p) = \sum_{i=1}^{N} J(k,i) p(i)$ where $J(k,i)$ is the fitness of an individual playing k if it interacts with an individual that plays strategy i.

Within quite general settings (Weibull 1995), the above replicator dynamics is known to converge to an ESS (which we introduce in the next section).

Evolutionary Games: Fitnesses

Consider an infinite population of players. Each individual i plays at times t_n^i, $n = 1, 2, 3, \ldots$ (assumed to constitute an independent Poisson process with some rate λ) a matrix game against some player $j(n)$ randomly selected within the population. The choice $j(n)$ of the other players at different times is independent. All players have the same finite space of pure strategies (also called actions) K. Each time it plays, a player may use a mixed strategy p, i.e., a probability measure over the set of pure strategies. We consider $J(k,i)$ (defined in the previous section) to be the payoff for a tagged individual if it uses a strategy k, and it interacts with an individual using strategy i. With some abuse of notation, one denotes by $J(p,q)$ the expected payoff for a player who uses a mixed strategy p when meeting another individual who adopts the mixed strategy q. If we define a payoff matrix A and consider p and q to be column vectors, then $J(p,q) = p'Aq$. The payoff function J is indeed linear in p and q. A strategy q is called a Nash equilibrium if

$$\forall p \in \Delta(K), \quad J(q,q) \geq J(p,q) \qquad (2)$$

where $\Delta(K)$ is the set of probabilities over the set K.

Suppose that the whole population uses a strategy q and that a small fraction ϵ (called "mutations") adopts another strategy p. Evolutionary forces are expected to select against p if

$$J(q, \epsilon p + (1 - \epsilon)q) > J(p, \epsilon p + (1 - \epsilon)q). \quad (3)$$

Evolutionary Stable Strategies: ESS

Definition 1 q is said to be an evolutionary stable strategy (ESS) if for every $p \neq q$ there exists some $\overline{\epsilon}_p > 0$ such that (3) holds for all $\epsilon \in (0, \overline{\epsilon}_p)$.

The definition of ESS is thus related to a robustness property against deviations by a whole (possibly small) fraction of the population. This is an important difference that distinguishes the equilibrium in populations as seen by biologists and the standard Nash equilibrium often used in economics context, in which robustness is defined against the possible deviation of a single user. Why do we need the stronger type of robustness? Since we deal with large populations, it is likely to be expected that from time to time, some group of individuals may deviate. Thus robustness against deviations by a single user is not sufficient to ensure that deviations will not develop and end up being used by a growing portion of the population.

Often ESS is defined through the following equivalent definition.

Theorem 1 (**Weibull 1995, Proposition 2.1 or Hofbauer and Sigmund 1998, Theorem 6.4.1, p 63**) *A strategy q is said to be an evolutionary stable strategy if and only if $\forall p \neq q$ one of the following conditions holds:*

$$J(q, q) > J(p, q), \quad (4)$$

or

$$J(q, q) = J(p, q) \text{ and } J(q, p) > J(p, p). \quad (5)$$

In fact, if condition (4) is satisfied, then the fraction of mutations in the population will tend to decrease (as it has a lower fitness, meaning a lower growth rate). Thus, the strategy q is then immune to mutations. If it does not but if still the condition (5) holds, then a population using q is "weakly" immune against a mutation using p. Indeed, if the mutant's population grows, then we shall frequently have individuals with strategy q competing with mutants. In such cases, the condition $J(q, p) > J(p, p)$ ensures that the growth rate of the original population exceeds that of the mutants.

A mixed strategy q that satisfies (4) for all $p \neq q$ is called strict Nash equilibrium. Recall that a mixed strategy q that satisfies (2) for all $p \neq q$ is a Nash equilibrium. We conclude from the above theorem that being a strict Nash equilibrium implies being an ESS, and being an ESS implies being a Nash equilibrium. Note that whereas a mixed Nash equilibrium is known to exist in a matrix game, an ESS may not exist. However, an ESS is known to exist in evolutionary games where the number of strategies available to each player is 2 (Weibull 1995).

Proposition 1 *In a symmetric game with two strategies for each player and no pure Nash equilibrium, there exists a unique mixed Nash equilibrium which is an ESS.*

Example: The Hawk and Dove Game

We briefly describe the hawk and dove game (Maynard Smith and Price 1973). A bird that searches food finds itself competing with another bird over food and has to decide whether to adopt a peaceful behavior (dove) or an aggressive one (hawk). The advantage of behaving aggressively is that in an interaction with a peaceful bird, the aggressive one gets access to all the food. This advantage comes at a cost: a hawk which meets another hawk ends up fighting with it and thus takes a risk of getting wounded. In contrast, two doves that meet in a contest over food share it without fighting. The fitnesses for player 1 (who chooses a row) are summarized in Table 1, in which the cost for fighting is taken to be some parameter $\delta > 1/2$.

This game has a unique mixed Nash equilibrium (and thus a unique ESS) in which the fraction p of aggressive birds is given by

Evolutionary Games, Table 1 The hawk-dove game

	H	D
H	$1/2 - \delta$	1
D	0	1/2

$$p = \frac{2}{1.5 + \delta}$$

Extension: Evolutionary Stable Sets

Assume that there are two mixed strategies p_i and p_j that have the same performance against each other, i.e., $J(p_i, p_j) = J(p_j, p_j)$. Then neither one of them can be an ESS, even if they are quite robust against other strategies. Now assume that when excluding one of them from the set of mixed strategies, the other one is an ESS. This could imply that different combinations of these two ESS's could coexist and would together be robust to any other mutations. This motivates the following definition of an ESSet (Cressman 2003):

Definition 2 A set E of symmetric Nash equilibria is an evolutionarily stable set (ESSet) if, for all $q \in E$, we have $J(q, p) > J(p, p)$ for all $p \notin E$ and such that $J(p, q) = J(q, q)$.

Properties of ESSet:

 (i) For all p and p' in an ESSet E, we have $J(p', p) = J(p, p)$.
 (ii) If a mixed strategy is an ESS, then the singleton containing that mixed strategy is an ESSet.
(iii) If the ESSet is not a singleton, then there is no ESS.
(iv) If a mixed strategy is in an ESSet, then it is a Nash equilibrium (see Weibull 1995, p. 48, Example 2.7).
 (v) Every ESSet is a disjoint union of Nash equilibria.
(vi) A perturbation of a mixed strategy which is in the ESSet can move the system to another mixed strategy in the ESSet. In particular, every ESSet is asymptotically stable for the replicator dynamics (Cressman 2003).

Summary and Future Directions

The entry has provided an overview of the foundations of evolutionary games which include the ESS (evolutionary stable strategy) equilibrium concept that is stronger than the standard Nash equilibrium and the modeling of the dynamics of the competition through the replicator dynamics. Evolutionary game framework is a first step in linking game theory to evolutionary processes. The payoff of a player is identified as its fitness, i.e., the rate of reproduction. Further development of this mathematical tool is needed for handling hierarchical fitness, i.e., the cases where the individual that interacts cannot be directly identified with the reproduction as it is part of a larger body. For example, the behavior of a blood cell in the human body when interacting with a virus cannot be modeled as directly related to the fitness of the blood cell but rather to that of the human body. A further development of the theory of evolutionary games is needed to define meaningful equilibrium notions and relate them to replication in such contexts.

Experiment Design and Identification for Control

Håkan Hjalmarsson
School of Electrical Engineering, ACCESS
Linnaeus Center, KTH Royal Institute of
Technology, Stockholm, Sweden

Abstract

Understanding the effect of experiment on estimation result is a crucial part of system identification – if the experiment is constrained or otherwise fixed, then the implied limitations need to be understood – but if the experiment can be designed, then given its fundamental importance that design parameter should be fully exploited, this entry will give an understanding of how it can be exploited. We also briefly discuss the particulars of identification for model-based control, one of the main applications of system identification.

Keywords

Introduction

The accuracy of an identified model is governed by:

(i) Information content in the data used for estimation

(ii) The complexity of the model structure

The former is related to the noise properties and the "energy" of the external excitation of the system and how it is distributed. In regard to (ii), a model structure which is not flexible enough to capture the true system dynamics will give rise to a systematic error, while an overly flexible model will be overly sensitive to noise (so-called overfitting). The model complexity is closely associated with the number of parameters used. For a linear model structure with n parameters modeling the dynamics, it follows from the invariance result in Rojas et al. (2009) that to obtain a model for which the variance of the frequency function estimate is less than $1/\gamma$ over all frequencies, the signal-to-noise ratio, as measured by input energy over noise variance, must be at least $n\gamma$. With energy being power $\times$ time and as input power is limited in physical systems, this indicates that the experiment time grows at least linearly with the number of model parameters. When the input energy budget is limited, the only way around this problem is to sacrifice accuracy over certain frequency intervals. The methodology to achieve this in a systematic way is known as experiment design.

Model Quality Measures

The Cramér-Rao bound provides a lower bound on the covariance matrix of the estimation error for an unbiased estimator. With $\hat{\theta}_N \in \mathbb{R}^n$ denoting the parameter estimate (based on N input–output samples) and θ_o the true parameters,

$$N\mathrm{E}\left[\left(\hat{\theta}_N - \theta_o\right)\left(\hat{\theta}_N - \theta_o\right)^T\right] \geq N\ I_F^{-1}(\theta_o, N) \tag{1}$$

where $I_F(\theta_o, N) \in \mathbb{R}^{n \times n}$ appearing in the lower bound is the so-called Fisher information matrix (Ljung 1999). For consistent estimators, i.e., when $\hat{\theta}_N \rightarrow \theta_o$ as $N \rightarrow \infty$, the inequality (1) typically holds asymptotically as the sample size N grows to infinity. The right-hand side in (1) is then replaced by the inverse of the per sample Fisher information $I_F(\theta_o) := \lim_{N\rightarrow\infty} I_F(\theta_o, N)/N$. An estimator is said to be asymptotically efficient if equality is reached in (1) as $N \rightarrow \infty$.

Even though it is possible to reduce the mean-square error by constraining the model flexibility appropriately, it is customary to use consistent estimators since the theory for biased estimators is still not well understood. For such estimators, using some function of the Fisher information as performance measure is natural.

General-Purpose Quality Measures

Over the years a number of "general-purpose" quality measures have been proposed. Perhaps the most frequently used is the determinant of the inverse Fisher information. This represents the volume of confidence ellipsoids for the parameter estimates and minimizing this measure is known as D-optimal design. Two other criteria relating to confidence ellipsoids are E-optimal design, which uses the length of the longest principal axis (the minimum eigenvalue of I_F) as quality measure, and A-optimal design, which uses the sum of the squared lengths of the principal axes (the trace of I_F^{-1}).

Application-Oriented Quality Measures

When demands are high and/or experimentation resources are limited, it is necessary to tailor the experiment carefully according to the intended use of the model. Below we will discuss a couple of closely related application-oriented measures.

Average Performance Degradation

Let $V_{\mathrm{app}}(\theta) \geq 0$ be a measure of how well the model corresponding to parameter θ performs when used in the application. In finance, V_{app} can, e.g., represent the ability to predict the stock market. In process industry, V_{app} can represent the profit gained using a feedback controller based on the model corresponding to θ. Let us assume that V_{app} is normalized such that $\min_\theta V_{\mathrm{app}}(\theta) = V_{\mathrm{app}}(\theta_o) = 0$. That V_{app} has minimum corresponding to the parameters of the true system is quite natural. We will call V_{app} the application cost. Assuming that the estimator is asymptotically efficient, using a second-order Taylor approximation gives that the average application cost can be expressed as (the first-order term vanishes since θ_o is the minimizer of V_{app})

$$\mathrm{E}\left[V_{\mathrm{app}}(\hat{\theta}_N)\right] \approx \frac{1}{2}\mathrm{E}\left[\left(\hat{\theta}_N - \theta_o\right)^T V_{\mathrm{app}}''(\theta_o)\left(\hat{\theta}_N - \theta_o\right)\right]$$
$$= \frac{1}{2N}\mathrm{Tr}\left\{V_{\mathrm{app}}''(\theta_o)I_F^{-1}(\theta_o)\right\} \tag{2}$$

This is a generalization of the A-optimal design measure and its minimization is known as L-optimal design.

Acceptable Performance

Alternatively, one may define a set of acceptable models, i.e., a set of models which will give acceptable performance when used in the application. With a performance degradation measure defined of the type V_{app} above, this would be a level set

$$\mathcal{E}_{\mathrm{app}} = \left\{\theta :\ V_{\mathrm{app}}(\theta) \leq \frac{1}{\gamma}\right\} \tag{3}$$

for some constant $\gamma > 0$. The objective of the experiment design is then to ensure that the

resulting estimate ends up in $\mathcal{E}_{\mathrm{app}}$ with high probability.

Design Variables

In an identification experiment there are a number of design variables at the user's disposal. Below we discuss three of the most important ones.

Sampling Interval
For the sampling interval, the general advice from an information theoretic point of view is to sample as fast as possible (Ljung 1999). However, sampling much faster than the time constants of the system may lead to numerical issues when estimating discrete time models as there will be poles close to the unit circle. Downsampling may thus be required.

Feedback
Generally speaking, feedback has three effects from an identification and experiment design point of view:

 (i) Not all the power in the input can be used to estimate the system dynamics when a noise model is estimated as a part of the input signal has to be used for the latter task; see Section 8.1 in Forssell and Ljung (1999). When a very flexible noise model is used, the estimate of the system dynamics then has to rely almost entirely on external excitation.
 (ii) Feedback can reduce the effect of disturbances and noise at the output. When there are constraints on the outputs, this allows for larger (input) excitation and therefore more informative experiments.
(iii) The cross-correlation between input and noise/disturbances requires good noise models to avoid biased estimates (Ljung 1999).

Strictly speaking, (i) is only valid when the system and noise models are parametrized separately. Items (i) and (ii) imply that when there are constraints on the input only, then the optimal design is always in open loop, whereas for output constrained only problems, the experiment

should be conducted in closed loop (Agüero and Goodwin 2007).

External Excitation Signals
The most important design variable is the external excitation, including the length of the experiment. Even for moderate experiment lengths, solving optimal experiment design problems with respect to the entire excitation sequence can be a formidable task. Fortunately, for experiments of reasonable length, the design can be split up in two steps:

 (i) First, optimization of the probability density function of the excitation
 (ii) Generation of the actual sequence from the obtained density function through a stochastic simulation procedure

More details are provided in section "Computational Issues."

Experimental Constraints

An experiment is always subject to constraints, physical as well as economical. Such constraints are typically translated into constraints on the following signal properties:

 (i) *Variability.* For example, too high level of excitation may cause the end product to go off-spec, resulting in product waste and associated high costs.
 (ii) *Frequency content.* Often, too harsh movements of the inputs may damage equipment.
(iii) *Amplitudes.* For example, actuators have limited range, restricting input amplitudes.
(iv) *Waveforms.* In process industry, it is not uncommon that control equipment limit the type of signals that can be applied. In other applications, it may be physically possible to realize only certain types of excitation. See section "Waveform Generation" for further discussion.

It is also often desired to limit the experiment time so that the process may go back to normal operation, reducing, e.g., cost of personnel. The latter is especially important in the process industry where dynamics are slow. The above type of constraints can be formulated as constraints on

the design variables in section "Design Variables" and associated variables.

Experiment Design Criteria

There are two principal ways to define an optimal experiment design problem:

(i) *Best effort.* Here the best quality as, e.g., given by one of the quality measures in section "Model Quality Measures" is sought under constraints on the experimental effort and cost. This is the classical problem formulation.

(ii) *Least-costly.* The cheapest experiment is sought that results in a predefined model quality. Thus, as compared to best effort design, the optimization criterion and constraint are interchanged. This type of design was introduced by Bombois and coworkers; see Bombois et al. (2006).

As shown in Rojas et al. (2008), the two approaches typically lead to designs only differing by a scaling factor.

Computational Issues

The optimal experiment design problem based on the Fisher information is typically non-convex. For example, consider a finite-impulse response model subject to an experiment of length N with the measured outputs collected in the vector

$$Y = \Phi\theta + E, \Phi = \begin{bmatrix} u(0) & \dots & u(-(n-1)) \\ \vdots & \vdots & \vdots \\ u(N-1) & \dots & u(N-n) \end{bmatrix}$$

where $E \in \mathbb{R}^N$ is zero-mean Gaussian noise with covariance matrix $\sigma^2 I_{N \times N}$. Then it holds that

$$I_F(\theta_o, N) = \frac{1}{\sigma^2}\Phi^T\Phi \qquad (4)$$

From an experiment design point of view, the input vector $u = \begin{bmatrix} u(-(n-1)) \dots u(N) \end{bmatrix}^T$ is the design Variable, but with the elements of $I_F(\theta_o, N)$ being a quadratic function of the input

sequence, all typical quality measures become non-convex.

While various methods for non-convex numerical optimization can be used to solve such problems, they often encounter problems with, e.g., local minima. To address this a number of techniques have been developed where either the problem is reparametrized so that it becomes convex or where a convex approximation is used. The latter technique is called convex relaxation and is often based on a reparametrization as well. We use the example above to provide a flavor of the different techniques.

Reparametrization

If the input is constrained to be periodic so that $u(t) = u(t + N)$, $t = -n, \dots, -1$, it follows that the Fisher information is linear in the sample correlations of the input. Using these as design variables instead of u results in that all quality measures referred to above become convex functions.

This reparametrization thus results in the two-step procedure discussed in section "External Excitation Signals": First, the sample correlations are obtained from an optimal experiment design problem, and then an input sequence is generated that has this sample correlation. In the second step there is a considerable freedom. Notice, however, that since correlations do not directly relate to the actual amplitudes of the resulting signals, it is difficult to incorporate waveform constraints in this approach. On the contrary, variance constraints are easy to incorporate.

Convex Relaxations

There are several approaches to obtain convex relaxations.

Using the per Sample Fisher Information

If the input is a realization of a stationary random process and the sample size N is large enough, $I_F(\theta_o, N)/N$ is approximately equal to the per sample Fisher matrix which only depends on the correlation sequence of the input. Using this approximation, one can now follow the same procedure as in the reparametrization approach and first optimize the input correlation sequence.

The generation of a stationary signal with a certain correlation is a stochastic realization problem which can be solved using spectral factorization followed by filtering white noise sequence, i.e., a sequence of independent identically distributed random variables, through the (stable) spectral factor (Jansson and Hjalmarsson 2005).

More generally, it turns out that the per sample Fisher information for linear models/systems only depends on the joint input/noise spectrum (or the corresponding correlation sequence). A linear parametrization of this quantity thus typically leads to a convex problem (Jansson and Hjalmarsson 2005).

The set of all spectra is infinite dimensional and this precludes a search over all possible spectra. However, since there is a finite-dimensional parametrization of the per sample Fisher information (it is a symmetric $n \times n$ matrix), it is also possible to find finite-dimensional sets of spectra that parametrize all possible per sample Fisher information matrices. Multisines with appropriately chosen frequencies is one possibility. However, even though all per sample Fisher information matrices can be generated, the solution may be suboptimal depending on which constraints the problem contains.

The situation for nonlinear problems is conceptually the same, but here the entire probability density function of the stationary process generating the input plays the same role as the spectrum in the linear case. This is a much more complicated object to parametrize.

Lifting

An approach that can deal with amplitude constraints is based on a so-called lifting technique: Introduce the matrix $U = uu^T$, representing all possible products of the elements of u. This constraint is equivalent to

$$\begin{bmatrix} U & u \\ u^T & 1 \end{bmatrix} \geq 0, \quad \text{rank} \begin{bmatrix} U & u \\ u^T & 1 \end{bmatrix} = 1 \qquad (5)$$

The idea of lifting is now to observe that the Fisher information matrix is linear in the elements of U and by dropping the rank constraint in (5) a convex relaxation is obtained, where both

U and u (subject to the matrix inequality in (5)) are decision variables.

Frequency-by-Frequency Design

An approximation for linear systems that allows frequency-by-frequency design of the input spectrum and feedback is obtained by assuming that the model is of high order. Then the variance of an nth-order estimate, $G(e^{i\omega}, \hat{\theta}_N)$, of the frequency function can approximately be expressed as

$$\text{Var } G(e^{i\omega}, \hat{\theta}_N) \approx \frac{n}{N} \frac{\Phi_v(\omega)}{\Phi_u(\omega)} \qquad (6)$$

(▶ System Identification: An Overview) in the open loop case (there is a closed-loop extension as well), where Φ_u and Φ_v are the input and noise spectra, respectively. Performance measures of the type (2) can then be written as

$$\int_{-\pi}^{\pi} W(e^{i\omega}) \frac{\Phi_v(\omega)}{\Phi_u(\omega)} d\omega$$

where the weighting $W(e^{i\omega}) \geq 0$ depends on the application. When only variance constraints are present, such problems can be solved frequency by frequency, providing both simple calculations and insight into the design.

Implementation

We have used the notation $I_F(\theta_o, N)$ to indicate that the Fisher information typically (but not always) depends on the parameter corresponding to the true system. That the optimal design depends on the to-be identified system is a fundamental problem in optimal experiment design. There are two basic approaches to address this problem which are covered below. Another important aspect is the choice of waveform for the external excitation signal. This is covered last in this section.

Robust Experiment Design

In robust experiment design, it is assumed that it is known beforehand that the true parameter belongs to some set, i.e., $\theta_o \in \Theta$. A minimax

approach is then typically taken, finding the experiment that minimizes the worst performance over the set Θ. Such optimization problems are computationally very difficult.

Adaptive Experiment Design

The alternative to robust experiment design is to perform the design adaptively or sequentially, meaning that first a design is performed based on some initial "guess" of the true parameter, and then as samples are collected, the design is revised taking advantage of the data information. Interestingly, the convergence rate of the parameter estimate is typically sufficiently fast that for this approach the asymptotic distribution is the same as for the design based on the true model parameter (Hjalmarsson 2009).

Waveform Generation

We have argued above that it is the spectrum of the excitation (together with the feedback) that determines the achieved model accuracy in the linear time-invariant case. In section "Using the per Sample Fisher Information" we argued that a signal with a particular spectrum can be obtained by filtering a white noise sequence through a stable spectral factor of the desired spectrum. However, we have also in section "Experimental Constraints" argued that particular applications may require particular waveforms. We will here elaborate further on how to generate a waveform with desired characteristics.

From an accuracy point of view, there are two general issues that should be taken into account when the waveform is selected:

- *Persistence of excitation.* A signal with a spectrum having n nonzero frequencies (on the interval $(-\pi, \pi]$) can be used to estimate at most n parameters. Thus, as is typically the case, if there is uncertainty regarding which model structure to use before the experiment, one has to ensure that a sufficient number of frequencies is excited.
- *The crest factor.* For all systems, the maximum input amplitude, say A, is constrained. To deal with this from an experiment design point of view, it is convenient to introduce what is called the crest factor of a signal:

$$C_r^2 = \frac{\max_t u^2(t)}{\lim_{N \to \infty} \frac{1}{N} \sum_{t=1}^{N} u^2(t)}$$

The crest factor is thus the ratio between the squared maximum amplitude and the power of the signal. Now, for a class of signal waveforms with a given crest factor, the input power that can be used is upper-bounded by

$$\lim_{N \to \infty} \frac{1}{N} \sum_{t=1}^{N} u^2(t) \leq \frac{A^2}{C_r^2} \tag{7}$$

However, the power is the integral of the signal spectrum, and since increasing the amplitude of the input signal spectrum will increase a model's accuracy, cf. (6), it is desirable to use as much signal power as possible. By (7) we see that this means that waveforms with low crest factor should be used.

A lower bound for the crest factor is readily seen to be 1. This bound is achieved for binary symmetric signals. Unfortunately, there exists no systematic way to design a binary sequence that has a prescribed spectrum. However, the so-called arcsin law may be used. It states that the sign of a zero-mean Gaussian process with correlation sequence r_τ gives a binary signal having correlation sequence $\tilde{r}_\tau = 2/\pi \arcsin(r_\tau)$. With $\tilde{r}_\tau$ given, one can try to solve this relation for the corresponding r_τ.

A crude, but often sufficient, method to generate binary sequences with desired spectral content is based on the use of *pseudorandom binary signals (PRBS)*. Such signals (which are generated by a shift register) are periodic signals which have correlation sequences similar to random white noise, i.e., a flat spectrum. By resampling such sequences, the spectrum can be modified. It should be noted that binary sequences are less attractive when it comes to identifying nonlinearities. This is easy to understand by considering a static system. If only one amplitude of the input is used, it will be impossible to determine whether the system is nonlinear or not.

A PRBS is a periodic signal and can therefore be split into its Fourier terms. With a period of M, each such term corresponds to one frequency on the grid $2\pi k/M$, $k = 0, \ldots, M - 1$. Such a signal can thus be used to estimate at most M parameters. Another way to generate a signal with period M is to add sinusoids corresponding to the above frequencies, with desired amplitudes. A periodic signal generated in this way is commonly referred to as a *MultiSine*. The crest factor of a multisine depends heavily on the relation between the phases of the sinusoids. times the number of sinusoids. It is possible to optimize the crest factor with respect to the choice of phases (Rivera et al. 2009). There exist also simple deterministic methods for choosing phases that give a good crest factor, e.g., Schroeder phasing. Alternatively, phases can be drawn randomly and independently, giving what is known as random-phase multisines (Pintelon and Schoukens 2012), a family of random signals with properties similar to Gaussian signals. Periodic signals have some useful features:

- *Estimation of nonlinearities.* A linear time-invariant system responds to a periodic input signal with a signal consisting of the same frequencies, but with different amplitudes and phases. Thus, it can be concluded that the system is nonlinear if the output contains other frequencies than the input. This can be explored in a systematic way to estimate also the nonlinear part of a system.

- *Estimation of noise variance.* For a linear time-invariant system, the difference in the output between different periods is due entirely to the noise if the system is in steady state. This can be used to devise simple methods to estimate the noise level.

- *Data compression.* By averaging measurements over different periods, the noise level can be reduced at the same time as the number of measurements is reduced.

Further details on waveform generation and general-purpose signals useful in system identification can be found in Pintelon and Schoukens (2012) and Ljung (1999).

Implications for the Identification Problem Per Se

In order to get some understanding of how optimal experimental conditions influence the identification problem, let us return to the finite-impulse response model example in section "Computational Issues." Consider a least-costly setting with an acceptable performance constraint. More specifically, we would like to use the minimum input energy that ensures that the parameter estimate ends up in a set of the type (3). An approximate solution to this is that a 99 % confidence ellipsoid for the resulting estimate is contained in $\mathcal{E}_{\text{app}}$. Now, it can be shown that a confidence ellipsoid is a level set for the average least-squares cost $\text{E}[V_N(\theta)] = \text{E}[\|Y - \Phi\theta\|^2] = \|\theta - \theta_o\|^2_{\Phi^T\Phi} + \sigma^2$. Assuming the application cost V_{app} also is quadratic in θ, it follows after a little bit of algebra (see Hjalmarsson 2009) that it must hold that

$$\text{E}[V_N(\theta)] \geq \sigma^2 \left(1 + \gamma c V_{\text{app}}(\theta)\right), \ \forall \theta \qquad (8)$$

for a constant c that is not important for our discussion. The value of $\text{E}[V_N(\theta)] = \|\theta - \theta_o\|^2_{\Phi^T\Phi} + \sigma^2$ is determined by how large the weighting $\Phi^T\Phi$ is, which in turn depends on how large the input u is. In a least-costly setting with the energy $\|u\|^2$ as criterion, the best solution would be that we have equality in (8). Thus we see that optimal experiment design tries to shape the identification criterion after the application cost. We have the following implications of this result:

(i) *Perform identification under appropriate scaling of the desired operating conditions.* Suppose that $V_{\text{app}}(\theta)$ is a function of how the system outputs deviate from a desired trajectory (determined by θ_o). Performing an experiment which performs the desired trajectory then gives that the sum of the squared prediction errors are an approximation of $V_{\text{app}}(\theta)$, at least for parameters close to θ_o. Obtaining equality in (8) typically requires an additional scaling

of the input excitation or the length of the experiment. The result is intuitively appealing: The desired operating conditions should reveal the system properties that are important in the application.

(ii) *Identification cost for application performance.* We see that the required energy grows (almost) linearly with γ, which is a measure of how close to the ideal performance (using the true parameter θ_o) we want to come. Furthermore, it is typical that as the performance requirements in the application increase, the sensitivity to model errors increases. This means that $V_{app}(\theta)$ increases, which thus in turn means that the identification cost increases. In summary, the identification cost will be higher, the higher performance that is required in the application. The inequality (8) can be used to quantify this relationship.

(iii) *Model structure sensitivity.* As V_{app} will be sensitive to system properties important for the application, while insensitive to system properties of little significance, with the identification criterion V_N matched to V_{app}, it is only necessary that the model structure is able to model the important properties of the system.

In any case, whatever model structure that is used, the identified model will be the best possible in that structure for the intended application. This is very different from an arbitrary experiment where it is impossible to control the model fit when a model of restricted complexity is used.

We conclude that optimal experiment design simplifies the overall system identification problem.

Identification for Control

Model-based control is one of the most important applications of system identification. Robust control ensures performance and stability in the presence of model uncertainty. However, the majority of such design methods do not employ the parametric ellipsoidal uncertainty sets resulting from standard system identification. In fact only in the last decade analysis and design tools for such type of model uncertainty have started to emerge, e.g., Raynaud et al. (2000) and Gevers et al. (2003).

The advantages of matching the identification criterion to the application have been recognized since long in this line of research. For control applications this typically implies that the identification experiment should be performed under the same closed-loop operation conditions as the controller to be designed. This was perhaps first recognized in the context of minimum variance control (see Gevers and Ljung 1986) where variance errors were the concern. Later on this was recognized to be the case also for the bias error, although here pre-filtering can be used to achieve the same objective.

To account for that the controller to be designed is not available, techniques where control and identification are iterated have been developed, cf. adaptive experiment design in section "Adaptive Experiment Design." Convergence of such schemes has been established when the true system is in the model set but has proved out of reach for models of restricted complexity.

In recent years, techniques integrating experiment design and model predictive control have started to appear. A general-purpose design criterion is used in Rathouský and Havlena (2013), while Larsson et al. (2013) uses an application-oriented criterion.

Summary and Future Directions

When there is the "luxury" to design the experiment, then this opportunity should be seized by the user. Without informative data there is little that can be done. In this exposé we have outlined the techniques that exist but also emphasized that a well-conceived experiment, reflecting the intended application, significantly can simplify the overall system identification problem.

Further developments of computational techniques are high on the agenda, e.g., how to handle

time-domain constraints and nonlinear models. To this end, developments in optimization methods are rapidly being incorporated. While, as reported in Hjalmarsson (2009), there are some results on how the identification cost depends on the performance requirements in the application, further understanding of this issue is highly desirable. Theory and further development of the emerging model predictive control schemes equipped with experiment design may very well be the direction that will have most impact in practice.

Explicit Model Predictive Control

Alberto Bemporad
IMT Institute for Advanced Studies Lucca,
Lucca, Italy

Abstract

Model predictive control (MPC) has been used in the process industries for more than 30 years because of its ability to control multivariable systems in an optimized way under constraints on input and output variables. Traditionally, MPC requires the solution of a quadratic program (QP) online to compute the control action, often restricting its applicability to slow processes. Explicit MPC completely removes the need for on-line solvers by precomputing the control law off-line, so that online operations reduce to a simple function evaluation. Such a function is piecewise affine in most cases, so that the MPC controller is equivalently expressed as a lookup table of linear gains, a form that is extremely easy to code, requires only basic arithmetic operations, and requires a maximum number of iterations that can be exactly computed a priori.

Keywords

Constrained control; Embedded optimization; Model predictive control; Multiparametric programming; Quadratic programming

Introduction

Model predictive control (MPC) is a well-known methodology for synthesizing feedback control laws that optimize closed-loop performance subject to prespecified operating constraints on inputs, states, and outputs (Borrelli et al. 2011; Mayne and Rawlings 2009). In MPC, the control action is obtained by solving a finite horizon open-loop optimal control problem at each sampling instant. Each optimization yields a sequence of optimal control moves, but only the first move is applied to the process: At the next time step, the computation is repeated over a shifted time horizon by taking the most recently available state information as the new initial condition of the new optimal control problem. For this reason, MPC is also called "receding horizon control." In most practical applications, MPC is based on a linear discrete-time time-invariant model of the controlled system and quadratic penalties on tracking errors and actuation efforts; in such a formulation, the optimal control problem can be recast as a quadratic programming (QP) problem, whose linear term of the cost function and right-hand side of the constraints depend on a vector of parameters that may change from one step to another (such as the current state and reference signals). To enable the implementation of MPC in real industrial products, a QP solution method must be embedded in the control hardware. The method must be fast enough to provide a solution within short sampling intervals and require simple hardware, limited memory to store the data defining the optimization problem and the code implementing the algorithm itself, a simple program code, and good worst-case estimates of the execution time to meet real-time system requirements.

Several *online* solution algorithms have been studied for embedding quadratic optimization in control hardware, such as active-set methods (Ricker 1985), interior-point methods (Wang and Boyd 2010), and fast gradient projection methods (Patrinos and Bemporad 2014). Explicit MPC takes a different approach to meet the above requirements, where multiparametric quadratic programming is proposed to pre-solve the QP

off-line, therefore converting the MPC law into a continuous and piecewise-affine function of the parameter vector (Bemporad et al. 2002b). We review the main ideas of explicit MPC in the next section, referring the reader to Alessio and Bemporad (2009) for a more complete survey paper on explicit MPC.

Model Predictive Control Problem

Consider the following finite-time optimal control problem formulation for MPC:

$$V^*(p) = \min_z \ \ell_N(x_N) + \sum_{k=0}^{N-1} \ell(x_k, u_k) \ \text{(1a)}$$

$$\text{s.t.} \ \ x_{k+1} = Ax_k + Bu_k \quad \text{(1b)}$$

$$C_x x_k + C_u u_k \leq c \quad \text{(1c)}$$

$$k = 0, \dots, N-1$$

$$C_N x_N \leq c_N \quad \text{(1d)}$$

$$x_0 = x \quad \text{(1e)}$$

where N is the prediction horizon; $x \in \mathbb{R}^m$ is the current state vector of the controlled system; $u_k \in \mathbb{R}^{n_u}$ is the vector of manipulated variables at prediction time k, $k = 0, \dots, N-1$; $z \triangleq [u_0' \cdots u_{N-1}']' \in \mathbb{R}^n$, $n \triangleq n_u N$, is the vector of decision variables to be optimized;

$$\ell(x, u) = \frac{1}{2}x'Qx + u'Ru \quad \text{(2a)}$$

$$\ell_N(x) = \frac{1}{2}x'Px \quad \text{(2b)}$$

are the stage cost and terminal cost, respectively; Q, P are symmetric and positive semidefinite matrices; and R is a symmetric and positive definite matrix.

Let $n_c \in \mathbb{N}$ be the number of constraints imposed at prediction time $k = 0, \dots, N-1$, namely, $C_x \in \mathbb{R}^{n_c \times m}$, $C_u \in \mathbb{R}^{n_c \times n_u}$, $c \in \mathbb{R}^{n_c}$, and let n_N be the number of terminal constraints, namely, $C_N \in \mathbb{R}^{n_N \times m}$, $c_N \in \mathbb{R}^{n_N}$. The total number q of linear inequality constraints imposed

in the MPC problem formulation (1) is $q = Nn_c + n_N$.

By eliminating the states $x_k = A^k x + \sum_{j=0}^{k-1} A^j Bu_{k-1-j}$ from problem (1), the optimal control problem (1) can be expressed as the convex quadratic program (QP):

$$V^\star(x) \triangleq \min_z \ \ \frac{1}{2}z'Hz + x'F'z + \frac{1}{2}x'Yx \quad \text{(3a)}$$

$$\text{s.t.} \ \ Gz \leq W + Sx \quad \text{(3b)}$$

where $H = H' \in \mathbb{R}^n$ is the Hessian matrix; $F \in \mathbb{R}^{n \times m}$ defines the linear term of the cost function; $Y \in \mathbb{R}^{m \times m}$ has no influence on the optimizer, as it only affects the optimal value of (3a); and the matrices $G \in \mathbb{R}^{q \times n}$, $S \in \mathbb{R}^{q \times m}$, $W \in \mathbb{R}^q$ define in a compact form the constraints imposed in (1). Because of the assumptions made on the weight matrices Q, R, P, matrix H is positive definite and matrix $\left[\begin{smallmatrix} H & F' \\ F & Y \end{smallmatrix}\right]$ is positive semidefinite.

The MPC control law is defined by setting

$$u(x) = [I \ 0 \ \dots \ 0]z(x) \quad \text{(4)}$$

where $z(x)$ is the optimizer of the QP problem (3) for the current value of x and I is the identity matrix of dimension $n_u \times n_u$.

Multiparametric Solution

Rather than using a numerical QP solver online to compute the optimizer $z(x)$ of (3) for each given current state vector x, the basic idea of explicit MPC is to pre-solve the QP off-line for the entire set of states x (or for a convex polyhedral subset $X \subseteq \mathbb{R}^m$ of interest) to get the optimizer function z, and therefore the MPC control law u, explicitly as a function of x.

The main tool to get such an explicit solution is *multiparametric quadratic programming* (mpQP). For mpQP problems of the form (3), Bemporad et al. (2002b) proved that the optimizer function $z^* : X_f \mapsto \mathbb{R}^n$ is piecewise affine and continuous over the set X_f of parameters x for which the problem is feasible (X_f is a polyhedral set, possibly $X_f = X$) and that
Explicit Model Predictive Control, Fig. 1 Explicit MPC solution for the double integrator example

the value function $V^* : X_f \mapsto \mathbb{R}$ associating with every $x \in X_f$ the corresponding optimal value of (3) is continuous, convex, and piecewise quadratic.

An immediate corollary is that the explicit version of the MPC control law u in (4), being the first n_u components of vector $z(x)$, is also a continuous and piecewise-affine state-feedback law defined over a partition of the set X_f of states into M polyhedral cells;

$$u(x) = \begin{cases} F_1 x + g_1 \text{ if } H_1 x \le K_1 \\ \quad\vdots \quad \vdots \\ F_M x + g_M \text{ if } H_M x \le K_M \end{cases} \quad (5)$$

An example of such a partition is depicted in Fig. 1. The explicit representation (5) has mapped the MPC law (4) into a lookup table of linear gains, meaning that for each given x, the values computed by solving the QP (3) online and those obtained by evaluating (5) are exactly the same.

Multiparametric QP Algorithms

A few algorithms have been proposed in the literature to solve the mpQP problem (3). All of them

construct the solution by exploiting the Karush-Kuhn-Tucker (KKT) conditions for optimality:

$$Hz + Fx + G'\lambda = 0 \quad (6a)$$

$$\lambda_i (G^i z - W^i - S^i x) = 0, \ \forall i = 1, \dots, q \quad (6b)$$

$$Gz \le W + Sx \quad (6c)$$

$$\lambda \ge 0 \quad (6d)$$

where $\lambda \in \mathbb{R}^q$ is the vector of Lagrange multipliers. For the strictly convex QP (3), conditions (6) are necessary and sufficient to characterize optimality.

An mpQP algorithm starts by fixing an arbitrary starting parameter vector $x_0 \in \mathbb{R}^m$ (e.g., the origin $x_0 = 0$), solving the QP (3) to get the optimal solution $z(x_0)$, and identifying the subset

$$\tilde{G}z(x) = \tilde{S}x + \tilde{W} \quad (7a)$$

of all constraints (6c) that are active at $z(x_0)$ and the remaining inactive constraints:

$$\hat{G}z(x) \le \hat{S}x + \hat{W} \quad (7b)$$

Correspondingly, in view of the complementarity condition (6b), the vector of Lagrange multipliers is split into two subvectors:

$$\tilde{\lambda}(x) \geq 0 \tag{8a}$$

$$\hat{\lambda}(x) = 0 \tag{8b}$$

We assume for simplicity that the rows of $\tilde{G}$ are linearly independent. From (6a), we have the relation

$$z(x) = -H^{-1}(Fx + \tilde{G}'\tilde{\lambda}(x)) \tag{9}$$

that, when substituted into (7a), provides

$$\tilde{\lambda}(x) = -\tilde{M}(\tilde{W} + (\tilde{S} + \tilde{G}H^{-1}F)x) \tag{10}$$

where $\tilde{M} = \tilde{G}'(\tilde{G}H^{-1}\tilde{G}')^{-1}$ and, by substitution in (9),

$$z(x) = H^{-1}(\tilde{M}\tilde{W} + \tilde{M}(\tilde{S} + \tilde{G}H^{-1}F)x - Fx) \tag{11}$$

The solution $z(x)$ provided by (11) is the correct one for all vectors x such that the chosen combination of active constraints remains optimal. Such all vectors x are identified by imposing constraints (7b) and (8a) on $z(x)$ and $\tilde{\lambda}(x)$, respectively, that leads to constructing the polyhedral set ("critical region"):

$$CR_0 = \{x \in \mathbb{R}^n : \tilde{\lambda}(x) \geq 0, \hat{G}z(x) \leq \hat{W} + \hat{S}x\} \tag{12}$$

Different mpQP solvers were proposed to cover the rest $X \setminus CR_0$ of the parameter set with other critical regions corresponding to new combinations of active constraints. The most efficient methods exploit the so-called "facet-to-facet" property of the multiparametric solution (Spjøtvold et al. 2006) to identify neighboring regions as in Tøndel et al. (2003a) and Baotić (2002). Alternative methods were proposed in Jones and Morari (2006), based on looking at (6) as a multiparametric linear complementarity problem, and in Patrinos and Sarimveis (2010), which provides algorithms for determining all neighboring regions even in the case the facet-to-facet property does not hold.

All methods handle the case of *degeneracy*, which may happen for some combinations of active constraints that are linearly dependent, that is, the associated matrix $\tilde{G}$ has no full row rank (in this case, $\tilde{\lambda}(x)$ may not be uniquely defined).

Extensions

The explicit approach described earlier can be extended to the following MPC setting:

$$\min_z \sum_{k=0}^{N-1} \frac{1}{2}(y_k - \mathbf{r_k})'Q_y(y_k - \mathbf{r_k}) + \frac{1}{2}\Delta u_k' R_\Delta \Delta u_k$$
$$+ (u_k - \mathbf{u_k^r})'R(u_k - \mathbf{u_k^r})' + \rho_\epsilon \epsilon^2 \tag{13a}$$

$$\text{s.t. } x_{k+1} = Ax_k + Bu_k + B_v \mathbf{v_k} \tag{13b}$$

$$y_k = Cx_k + D_u u_k + D_v \mathbf{v_k} \tag{13c}$$

$$u_k = u_{k-1} + \Delta u_k, \ k = 0, \ldots, N-1 \tag{13d}$$

$$\Delta u_k = 0, \ k = N_u, \ldots, N-1 \tag{13e}$$

$$\mathbf{u_{min}^k} \leq u_k \leq \mathbf{u_{max}^k}, k = 0, \ldots, N_u - 1 \tag{13f}$$

$$\Delta \mathbf{u_{min}^k} \leq \Delta u_k \leq \Delta \mathbf{u_{max}^k}, \ k = 0, \ldots, N_u - 1 \tag{13g}$$

$$\mathbf{y_{min}^k} - \epsilon V_{min} \leq y_k \leq \mathbf{y_{max}^k} + \epsilon V_{max} \tag{13h}$$
$$k = 0, \ldots, N_c - 1$$

where R_Δ is a symmetric and positive definite matrix; matrices Q_y and R are symmetric and positive semidefinite; $\mathbf{v_k}$ is a vector of measured disturbances; y_k is the output vector; $\mathbf{r_k}$ its corresponding reference to be tracked; Δu_k is the vector of input increments; $\mathbf{u_k^r}$ is the input reference; $\mathbf{u_{min}^k}$, $\mathbf{u_{max}^k}$, $\Delta \mathbf{u_{min}^k}$, $\Delta \mathbf{u_{max}^k}$, $\mathbf{y_{min}^k}$, $\mathbf{y_{max}^k}$ are bounds; and N, N_u, N_c are, respectively, the prediction, control, and constraint horizons. The extra variable ϵ is introduced to soften output constraints, penalized by the (usually large) weight ρ_ϵ in the cost function (13a).

Everything marked in bold-face in (13), together with the command input u_{-1} applied at the previous sampling step and the current state x, can be treated as a parameter with respect to

which to solve the mpQP problem and obtain the explicit form of the MPC controller. For example, for a tracking problem with no anticipative action ($\mathbf{r_k} \equiv r_0, \forall k = 0, \ldots, N-1$), no measured disturbance, and fixed upper and lower bounds, the explicit solution is a continuous piecewise affine function of the parameter vector $\begin{bmatrix} x \\ r_0 \\ u_{-1} \end{bmatrix}$. Note that prediction models and/or weight matrices in (13) cannot be treated as parameters to maintain the mpQP formulation (3).

Linear MPC Based on Convex Piecewise-Affine Costs

A similar setting can be repeated for MPC problems based on linear prediction models and convex piecewise-affine costs, such as 1- and ∞-norms. In this case, the MPC problem is mapped into a multiparametric linear programming (mpLP) problem, whose solution is again continuous and piecewise-affine with respect to the vector of parameters. For details, see Bemporad et al. (2002a).

Robust MPC

Explicit solutions to min-max MPC problems that provide robustness with respect to additive and/or multiplicative unknown-but-bounded uncertainty were proposed in Bemporad et al. (2003), based on a combination of mpLP and dynamic programming. Again the solution is piecewise affine with respect to the state vector.

Hybrid MPC

An MPC formulation based on 1- or ∞-norms and hybrid dynamics expressed in mixed-logical dynamical (MLD) form can be solved explicitly by treating the optimization problem associated with MPC as a multiparametric mixed integer linear programming (mpMILP) problem. The solution is still piecewise affine but may be discontinuous, due to the presence of binary variables (Bemporad et al. 2000). A better approach based on dynamic programming combined with mpLP (or mpQP) was proposed in Borrelli et al. (2005) for hybrid systems in piecewise-affine (PWA) dynamical form and linear (or quadratic) costs.

Applicability of Explicit MPC

Complexity of the Solution

The complexity of the solution is given by the number M of regions that form the explicit solution (5), dictating the amount of memory to store the parametric solution (F_i, G_i, H_i, K_i, $i = 1, \ldots, M$), and the worst-case execution time required to compute $F_i x + G_i$ once the problem of identifying the index i of the region $\{x : H_i x \leq K_i\}$ containing the current state x is solved (which usually takes most of the time). The latter is called the "point location problem," and a few methods have been proposed to solve the problem more efficiently than searching linearly through the list of regions (see, e.g., the tree-based approach of Tøndel et al. 2003b).

An upper bound to M is 2^q, which is the number of all possible combinations of active constraints. In practice, M is much smaller than 2^q, as most combinations are never active at optimality for any of the vectors x (e.g., lower and upper limits on an actuation signal cannot be active at the same time, unless they coincide). Moreover, regions in which the first n_u component of the multiparametric solution $z(x)$ is the same can be joined together, provided that their union is a convex set (an optimal merging algorithm was proposed by Geyer et al. (2008) to get a minimal number M of partitions). Nonetheless, the complexity of the explicit MPC law typically grows exponentially with the number q of constraints. The number m of parameters is less critical and mainly affects the number of elements to be stored in memory (i.e., the number of columns of matrices F_i, H_i). The number n of free variables also affects the number M of regions, mainly because they are usually upper and lower bounded.

Computer-Aided Tools

The Model Predictive Control Toolbox (Bemporad et al. 2014) offers functions for designing explicit MPC controllers in MATLAB since 2014. Other tools exist such as the Hybrid Toolbox (Bemporad 2003) and the Multi-Parametric Toolbox (Kvasnica et al. 2006).

Summary and Future Directions

Explicit MPC is a powerful tool to convert an MPC design into an equivalent control law that can be implemented as a lookup table of linear gains. Whether the explicit form is preferable to solving the QP problem online depends on available CPU time, data memory, and program memory and other practical considerations. Although suboptimal methods have been proposed to reduce the complexity of the control law, still the explicit MPC approach remains convenient for relatively small problems (such as one or two command inputs, short control and constraint horizons, up to ten states). For larger problems, and/or problems that are linear time varying, on line QP solution methods tailored to embedded MPC may be preferable.

Recommended Reading

For getting started in explicit MPC, we recommend reading the paper by Bemporad et al. (2002b) and the survey paper Alessio and Bemporad (2009). Hands-on experience using one of the MATLAB tools listed above is also useful for fully appreciating the potentials and limitations of explicit MPC. For understanding how to program a good multiparametric QP solver, the reader is recommended to take the approach of Tøndel et al. (2003a) and Spjøtvold et al. (2006) or, in alternative, of Patrinos and Sarimveis (2010) or Jones and Morari (2006).

Extended Kalman Filters

Frederick E. Daum
Raytheon Company, Woburn, MA, USA

Synonyms

EKF

Abstract

The extended Kalman filter (EKF) is the most popular estimation algorithm in practical applications. It is based on a linear approximation to the Kalman filter theory. There are thousands of variations of the basic EKF design, which are intended to mitigate the effects of nonlinearities, non-Gaussian errors, ill-conditioning of the covariance matrix and uncertainty in the parameters of the problem.

Keywords

Estimation; Nonlinear filters

The extended Kalman filter (EKF) is by far the most popular nonlinear filter in practical engineering applications. It uses a linear approximation to the nonlinear dynamics and measurements and exploits the Kalman filter theory, which is optimal for linear and Gaussian problems; Gelb (1974) is the most accessible but thorough book on the EKF. The real-time computational complexity of the EKF is rather modest; for example, one can run an EKF with high-dimensional state vectors ($d =$ several hundreds) in real time on a single microprocessor chip. The computational complexity of the EKF scales as the cube of the dimension of the state vector (d) being estimated. The EKF often gives good estimation accuracy for practical nonlinear problems, although the EKF accuracy can be very poor for difficult nonlinear non-Gaussian problems. There are many different variations of EKF algorithms, most of which are intended to improve estimation accuracy. In particular, the following types of EKFs are common in engineering practice: (1) second-order Taylor series expansion of the nonlinear functions, (2) iterated measurement updates that recompute the point at which the first order Taylor series is evaluated for a given measurement, (3) second-order iterated (i.e., combination of items 1 and 2), (4) special coordinate systems (e.g., Cartesian, polar or spherical, modified polar or spherical, principal axes of the covariance matrix ellipse, hybrid coordinates, quaternions rather than Euler angles, etc.), (5) preferred order of processing sequential scalar measurement updates, (6) decoupled or partially decoupled or quasi-decoupled covariance matrices, and many more variations. In fact, there is no such thing as "the" EKF, but rather there are thousands of different versions of the EKF. There are also many different versions of the Kalman filter itself, and all of these can be used to design EKFs as well. For example, there are many different equations to update the Kalman filter error covariance matrices with the intent of mitigating ill-conditioning and improving robustness, including (1) square-root factorization of the covariance matrix, (2) information matrix update, (3) square-root information update, (4) Joseph's robust version of the covariance matrix update, (5) at least three distinct algebraic versions of the covariance matrix update, as well as hybrids of the above.

Many of the good features of the Kalman filter are also enjoyed by the EKF, but unfortunately not all. For example, we have a very good theory of stability for the Kalman filter, but there is no theory that guarantees that an EKF will be stable in practical applications. The only method

to check whether the EKF is stable is to run Monte Carlo simulations that cover the relevant regions in state space with the relevant measurement parameters (e.g., data rate and measurement accuracy). Secondly, the Kalman filter computes the theoretical error covariance matrix, but there is no guarantee that the error covariance matrix computed by the EKF approximates the actual filter errors, but rather the EKF covariance matrix could be optimistic by orders of magnitude in real applications. Third, the numerical values of the process noise covariance matrix can be computed theoretically for the Kalman filter, but there is no guarantee that these will work well for the EKF, but rather engineers typically tune the process noise covariance matrix using Monte Carlo simulations or else use a heuristic adaptive process (e.g., IMM). All of these short-comings of the EKF compared with the Kalman filter theory are due to a myriad of practical issues, including (1) nonlinearities in the dynamics or measurements, (2) non-Gaussian measurement errors, (3) unmodeled measurement error sources (e.g., residual sensor bias), (4) unmodeled errors in the dynamics, (5) data association errors, (6) unresolved measurement data, (7) ill-conditioning of the covariance matrix, etc. The actual estimation accuracy of an EKF can only be gauged by Monte Carlo simulations over the relevant parameter space.

The actual performance of an EKF can depend crucially on the specific coordinate system that is used to represent the state vector. This is extremely well known in practical engineering applications (e.g., see Mehra 1971; Stallard 1991; Miller 1982; Markley 2007; Daum 1983; Schuster 1993). Intuitively, this is because the dynamics and measurement equations can be exactly linear in one coordinate system but not another; this is very easy to see; start with dynamics and measurements that are exactly linear in Cartesian coordinates and transform to polar coordinates and we will get highly nonlinear equations. Likewise, we can have approximately linear dynamics and measurements in a specific coordinate system but highly nonlinear equations in another coordinate system. But in theory, the optimal estimation accuracy does not depend on the coordinate system. Moreover, in math and physics, coordinate-free methods are preferred, owing to their greater generality and simplicity and power. The physics does not depend on the specific coordinate system; this is essentially a definition of what "physics" means, and it has resulted in great progress in physics over the last few hundred years (e.g., general relativity, gauge invariance in quantum field theory, Lorentz invariance in special relativity, as well as a host of conservation laws in classical mechanics that are explained by Noether's theorem which relates invariance to conserved quantities). Similarly in math, coordinate-free methods have been the royal road to progress over the last 100 years but not so for practical engineering of EKFs, because EKFs are approximations rather than being exact, and the accuracy of the EKF approximation depends crucially on the specific coordinate system used. Moreover, the effect of ill-conditioning of the covariance matrices in EKFs depends crucially on the specific coordinate system used in the computer; for example, if we could compute the EKF in principal coordinates, then the covariance matrices would be diagonal, and there would be no effect of ill-conditioning, despite enormous condition numbers of the covariance matrices. Surprisingly, these two simple points about coordinate systems are still not well understood by many researchers in nonlinear filtering.

Extremum Seeking Control

Miroslav Krstic
Department of Mechanical and Aerospace Engineering, University of California, San Diego, La Jolla, CA, USA

Abstract

Extremum seeking (ES) is a method for real-time non-model-based optimization. Though ES was invented in 1922, the "turn of the twenty-first century" has been its golden age, both in terms of the development of theory and in terms of its adoption in industry and in fields outside of control engineering. This entry overviews basic gradient- and Newton-based versions of extremum seeking with periodic and stochastic perturbation signals.

Keywords

Gradient climbing; Newton's method

The Basic Idea of Extremum Seeking

Many versions of extremum seeking exist, with various approaches to their stability study (Krstic and Wang 2000; Liu and Krstic 2012; Tan et al.

Extremum Seeking Control, Fig. 1 The simplest perturbation-based extremum seeking scheme for a quadratic single-input map $f(\theta) = f^* + \dfrac{f''}{2}(\theta - \theta^*)^2$, where f^*, f'', θ^* are all unknown. The user has to only know the sign of f'', namely, whether the quadratic map has a maximum or a minimum, and has to choose the adaptation gain k such that $\mathrm{sgn}\,k = -\mathrm{sgn}\,f''$. The user has to also choose the frequency ω as relatively large compared to a, k, and f''

2006). The most common version employs perturbation signals for the purpose of estimating the gradient of the unknown map that is being optimized. To understand the basic idea of extremum seeking, it is best to first consider the case of a static single-input map of the quadratic form, as shown in Fig. 1.

Three different thetas appear in Fig. 1: θ^* is the unknown optimizer of the map, $\hat{\theta}(t)$ is the real-time estimate of θ^*, and $\theta(t)$ is the actual input into the map. The actual input $\theta(t)$ is based on the estimate $\hat{\theta}(t)$ but is perturbed by the signal $a\sin(\omega t)$ for the purpose of estimating the unknown gradient $f'' \cdot (\theta - \theta^*)$ of the map $f(\theta)$. The sinusoid is only one choice for a perturbation signal – many other perturbations, from square waves to stochastic noise, can be used in lieu of sinusoids, provided they are of zero mean. The estimate $\hat{\theta}(t)$ is generated with the integrator k/s with the adaptation gain k controlling the speed of estimation.

The ES algorithm is successful if the error between the estimate $\hat{\theta}(t)$ and the unknown θ^*, namely, the signal

$$\tilde{\theta}(t) = \hat{\theta}(t) - \theta^* \tag{1}$$

converges towards zero. Based on Fig. 1, the estimate is governed by the differential equation $\dot{\hat{\theta}} = k \sin(\omega t) f(\theta)$, which means that the estimation error is governed by

$$\frac{\mathrm{d}\tilde{\theta}}{\mathrm{d}t} = ka \sin(\omega t) \left[f^* + \frac{f''}{2} \left(\tilde{\theta} + a \sin(\omega t) \right)^2 \right] \tag{2}$$

Expanding the right-hand side, one obtains

$$\frac{\mathrm{d}\tilde{\theta}(t)}{\mathrm{d}t} = kaf^* \underbrace{\sin(\omega t)}_{\text{mean}=0} + ka^3 \frac{f''}{2} \underbrace{\sin^3(\omega t)}_{\text{mean}=0}$$

$$+ ka \frac{f''}{2} \underbrace{\sin(\omega t)}_{\text{fast, mean}=0} \underbrace{\tilde{\theta}(t)^2}_{\text{slow}}$$

$$+ ka^2 f'' \underbrace{\sin^2(\omega t)}_{\text{fast, mean}=1/2} \underbrace{\tilde{\theta}(t)}_{\text{slow}} \tag{3}$$

A theoretically rigorous time-averaging procedure allows to replace the above sinusoidal signals by their means, yielding the "average system"

$$\frac{\mathrm{d}\tilde{\theta}_{\text{ave}}}{\mathrm{d}t} = \overbrace{\frac{kf'' a^2}{2}}^{<0} \tilde{\theta}_{\text{ave}}, \tag{4}$$

which is exponentially stable. The averaging theory guarantees that there exists sufficiently large ω such that, if the initial estimate $\hat{\theta}(0)$ is sufficiently close to the unknown θ^*,

$$|\theta(t) - \theta^*| \le |\theta(0) - \theta^*| e^{\frac{kf''a^2}{2}t} + O\left(\frac{1}{\omega}\right)$$

$$+ a, \qquad \forall t \ge 0. \tag{5}$$

For the user, the inequality (5) guarantees that, if a is chosen small and ω is chosen large, the input $\theta(t)$ exponentially converges to a small interval around the unknown θ^* and, consequently, the output $f(\theta(t))$ converges to the vicinity of the optimal output f^*.
Extremum Seeking Control, Fig. 2 Extremum seeking algorithm for a multivariable map $y = Q(\theta)$, where θ is the input vector $\theta = [\theta_1, \theta_2, \cdots, \theta_n]^T$. The algorithm employs the additive perturbation vector signal $S(t)$ given in (6) and the multiplicative demodulation vector signal $M(t)$ given in (7)

ES for Multivariable Static Maps

For static maps, ES extends in a straightforward manner from the single-input case shown in Fig. 1 to the multi-input case shown in Fig. 2.

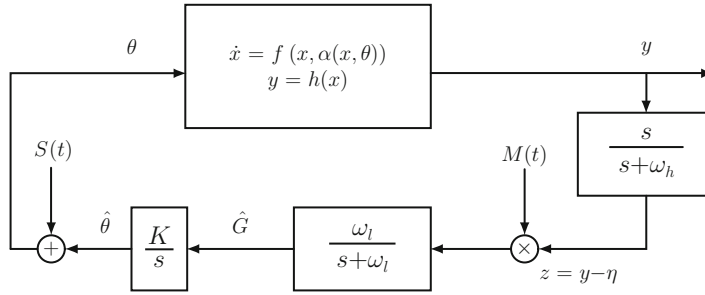
The algorithm measures the scalar signal $y(t) = Q(\theta(t))$, where $Q(\cdot)$ is an unknown map whose input is the vector $\theta = [\theta_1, \theta_2, \cdots, \theta_n]^T$. The gradient is estimated with the help of the signals

$$S(t) = \begin{bmatrix} a_1 \sin(\omega_1 t) & \cdots & a_n \sin(\omega_n t) \end{bmatrix}^T \tag{6}$$

$$M(t) = \begin{bmatrix} \dfrac{2}{a_1} \sin(\omega_1 t) & \cdots & \dfrac{2}{a_n} \sin(\omega_n t) \end{bmatrix}^T \tag{7}$$

with nonzero perturbation amplitudes a_i and with a gain matrix K that is diagonal. To guarantee convergence, the user should choose $\omega_i \ne \omega_j$. This is a key condition that differentiates the multi-input case from the single-input case. In addition, for simplicity in the convergence analysis, the user should choose ω_i/ω_j as rational and $\omega_i + \omega_j \ne \omega_k$ for distinct i, j, and k.

If the unknown map is quadratic, namely, $Q(\theta) = Q^* + \frac{1}{2}(\theta - \theta^*)^T H(\theta - \theta^*)$, the averaged system is

$$\dot{\tilde{\theta}}_{\text{ave}} = KH\tilde{\theta}_{\text{ave}}, \qquad H = \text{Hessian}. \tag{8}$$


Extremum Seeking Control, Fig. 3 The ES algorithm in the presence of dynamics with an equilibrium map $\theta \mapsto y$ that satisfies the same conditions as in the static case. If the dynamics are stable and the user employs parameters in the ES algorithm that make the algorithm dynamics slower than the dynamics of the plant, convergence is guaranteed (at least locally). The two filters are useful in the implementation to reduce the adverse effect of the perturbation signals on asymptotic performance but are not needed in the stability analysis

If, for example, the map $Q(\cdot)$ has a maximum that is locally quadratic (which implies $H = H^T < 0$) and if the user chooses the elements of the diagonal gain matrix K as positive, the ES algorithm is guaranteed to be locally convergent. However, the convergence rate depends on the unknown Hessian H. This weakness of the gradient-based ES algorithm is removed with the Newton-based ES algorithm.

A stochastic version of the algorithm in Fig. 2 also exists, in which $S(t)$ and $M(t)$ are replaced by

$$S(\eta(t)) = [a_1 \sin(\eta_1(t)), \ldots, a_n \sin(\eta_n(t))]^T,$$

$$\tag{9}$$

$$M(\eta(t)) = \left[\frac{2}{a_1(1 - e^{-q_1^2})} \sin(\eta_1(t)), \ldots, \right.$$

$$\left. \frac{2}{a_n(1 - e^{-q_n^2})} \sin(\eta_n(t)) \right]^T \tag{10}$$

where $\eta_i = \dfrac{q_i \sqrt{\varepsilon_i}}{\varepsilon_i s + 1} [\dot{W}_i]$ and $\dot{W}_i$ are independent unity-intensity white noise processes.

ES for Dynamic Systems

ES extends in a relatively straightforward manner from static maps to dynamic systems, provided the dynamics are stable and the algorithm's parameters are chosen so that the algorithm's dynamics are slower than those of the plant. The algorithm is shown in Fig. 3.

The technical conditions for convergence in the presence of dynamics are that the equilibria $x = l(\theta)$ of the system $\dot{x} = f(x, \alpha(x, \theta))$, where $\alpha(x, \theta)$ is the control law of an internal feedback loop, are locally exponentially stable uniformly in θ and that, given the output map $y = h(x)$, there exists at least one $\theta^* \in \mathbb{R}^n$ such that $\dfrac{\partial}{\partial \theta}(h \circ l)(\theta^*) = 0$ and $\dfrac{\partial^2}{\partial \theta^2}(h \circ l)(\theta^*) = H < 0$, $H = H^T$.

The stability analysis in the presence of dynamics employs both averaging and singular perturbations, in a specific order. The design guidelines for the selection of the algorithm's parameters follow the analysis. Though the guidelines are too lengthy to state here, they ensure that the plant's dynamics are on a fast time scale, the perturbations are on a medium time scale, and the ES algorithm is on a slow time scale.

Newton ES Algorithm for Static Map

A Newton version of the ES algorithm, shown in Fig. 4, ensures that the convergence rate be user assignable, rather than being dependent on the unknown Hessian of the map.

The elements of the demodulating matrix $N(t)$ for generating the estimate of the Hessian are given by
Extremum Seeking Control, Fig. 4 A Newton-based ES algorithm for a static map. The multiplicative excitation $N(t)$ helps generate the estimate of Hessian $\dfrac{\partial^2 Q(\theta)}{\partial \theta^2}$

as $\hat{H}(t) = N(t)y(t)$. The Riccati matrix differential equation $\Gamma(t)$ generates an estimate of the Hessian's *inverse* matrix, avoiding matrix inversions of Hessian estimates that may be singular during the transient

$$N_{ii}(t) = \frac{16}{a_i^2}\Big(\sin^2(\omega_i t) - \frac{1}{2}\Big),$$

$$N_{ij}(t) = \frac{4}{a_i a_j}\sin(\omega_i t)\sin(\omega_j t) \qquad (11)$$

For a quadratic map, the averaged system in error variables $\tilde{\theta} = \hat{\theta} - \theta^*$, $\tilde{\Gamma} = \Gamma - H^{-1}$ is

$$\frac{d\tilde{\theta}^{\text{ave}}}{dt} = -K\tilde{\theta}^{\text{ave}} - K\underbrace{\tilde{\Gamma}^{\text{ave}}H\tilde{\theta}^{\text{ave}}}_{\text{quadratic}},$$

$$\frac{d\tilde{\Gamma}^{\text{ave}}}{dt} = -\omega_r\tilde{\Gamma}^{\text{ave}} - \omega_r\underbrace{\tilde{\Gamma}^{\text{ave}}H\tilde{\Gamma}^{\text{ave}}}_{\text{quadratic}}. \quad (12)$$

Since the eigenvalues are determined by K and ω_r and are therefore independent of the unknown H, the (local) convergence rate is user assignable.

Further Reading on Extremum Seeking

Since the publication of the first proof of stability of extremum seeking (Krstic and Wang 2000), thousands of papers have been published

on this topic, presenting further theoretical developments and applications of ES. A proof that expands the validity of extremum seeking from local to global stability was published in Tan et al. (2006). The book Liu and Krstic (2012) presents stochastic versions of the algorithms in this entry, where the sinusoids are replaced by filtered white noise perturbation signals.

FDD

Abstract

The fundamental concepts and methods of fault detection and diagnosis are reviewed. Faults are defined and classified as additive or multiplicative. The model-free approach of alarm systems is described and critiqued. Residual generation, using the mathematical model of the plant, is introduced. The propagation of additive and multiplicative faults to the residuals is discussed, followed by a review of the effect of disturbances, noise, and model errors. Enhanced residuals (structured and directional) are introduced. The main residual generation techniques are briefly described, including direct consistency relations, parity space, and diagnostic observers. Principal component analysis and its application to fault detection and diagnosis are outlined. The article closes with some thoughts about future directions.

Keywords

Consistency relations; Diagnostic observers; Fault detection; Fault diagnosis; Parity space; Principal component analysis; Residual generation

Introduction

Faults are malfunctions of various elements of technical systems. Extreme cases of faults, called *failures*, are catastrophic breakdowns of the same. The technical systems (*the plant*) we are concerned with range from complex production systems (chemical plants, oil refineries, power stations) through major transportation equipment (airplanes, ships) to consumer machines (automobiles, home-heating systems, etc.). The faults may affect various parts of the main technical system (motors, pumps, storage tanks, pipelines) or devices interfacing the main technical system with computers providing for control, monitoring, and operator information. These latter include *sensors* (measuring devices) and *actuators* (devices acting on the process, such as valves).

The objective of *fault detection* is to determine and signal if there is a fault anywhere in the system. *Fault diagnosis* is aimed at providing more specific information about the fault; *fault isolation* is to pinpoint at the component(s) (sensors, actuators, or plant components) where the fault is located, while *fault identification* is to determine (estimate) the size of the fault and, in

some cases, the time of its arrival. With the ubiquitous presence of the computer, fault detection and diagnosis (FDD) is, in general, a function of the computer interfaced to the plant.

The simplest approaches to FDD consist of comparing individual plant measurements to preset limits, without utilizing any knowledge of the plant model (*limit checking* or *alarm systems*). More sophisticated techniques rely on an explicit mathematical model of the plant. They compare plant measurements to estimates obtained, from other measurements, by the model; any discrepancy may be an indication of faults. Another class of techniques (generally but incorrectly called "*data driven*"), most notably principal component analysis (PCA), include the estimation of an implicit model, from empirical plant data, and then use this in ways similar to the model-based methods. These approaches will be described in more detail in the sequel.

Alarm Systems

Alarm systems rely on the comparison of individual plant measurements to their respective limits. The limits may be two or one sided (upper and lower limit or upper limit only) and may have one or two levels (preliminary and full alarm). Momentary comparisons may be extended to include trend checks. Alarm systems are relatively simple but suffer from two major shortcomings:

– They have very limited fault specificity. A variable exceeding its limit is not a fault but a symptom of faults. A single-component fault may cause alarm on many variables and a particular alarm may be due to various component faults.
– They have limited fault sensitivity. What is "normal" for a plant output variable depends on the value of the plant inputs. Such relationship, however, cannot be considered without a plant model; therefore, the alarm thresholds need to be set conservatively high.

Because of their simplicity, and in spite of the above shortcomings, alarm systems are widely used in industrial applications.

Model-Based FDD Concepts

Model-based methods utilize an explicit mathematical model of the plant. Such model is obtained usually from empirical plant data by systems identification methods or, exceptionally, from the "first principles" understanding of the plant. Model building, though critical to the success of model-based FDD, is usually not considered part of the FDD effort. The models may be linear or nonlinear, static or dynamic, and continuous or discrete time. In FDD, most frequently linear discrete-time dynamic models are used.

The fundamental idea of model-based FDD is the comparison of measured plant outputs to their estimates, obtained, via the mathematical model, from measured or actuated plant inputs (Fig. 1). Any discrepancy is (at least ideally) an indication that a fault (or faults) is (are) present in the system. Mathematically, the difference between the measured output $y_i(t)$ and its estimate $y_i{}^{\wedge}(t)$ is a (primary) residual (Willsky 1976):

$$e_i(t) = y_i(t) - y_i{}^{\wedge}(t)$$

In general, residuals are quantities that are zero in the absence of faults and nonzero in their presence.

Unfortunately, it is not only the faults that can make the residuals nonzero. Usually, the plant is subject to disturbances (unmeasured determin-
Fault Detection and Diagnosis, Fig. 1 Analytical redundancy

istic inputs) and noise (unmeasured random inputs) (Fig. 1). In addition, and most importantly, model-based FDD is subject to model errors (due either to initial inaccuracies in model building or to changes in the physical plan). The FDD algorithm should be designed, as much as possible, to be insensitive to noise and "*robust*" in face of disturbances and model errors.

Additive and multiplicative faults. Depending on the way they appear in the system equations, faults may be additive or multiplicative. Additive faults are sensor and actuator biases, leaks in the plant, etc. Multiplicative faults are changes in the plant parameters. In the following input-output relationship, $\mathbf{u}(t)$ is the vector of observed (measured or commanded) plant inputs, $\mathbf{y}(t)$ is the vector of measured plant outputs, and $\mathbf{p}(t)$ is the vector of additive faults and t is the discrete time. $\mathbf{M}(q)$ and $\mathbf{S}(q)$ are transfer function matrices in the shift operator q, and $\boldsymbol{\theta}$ is the vector of plant parameters. Then,

$$\mathbf{y}(t) = \mathbf{M}(q, \boldsymbol{\theta})\mathbf{u}(t) + \mathbf{S}(q, \boldsymbol{\theta})\mathbf{p}(t)$$

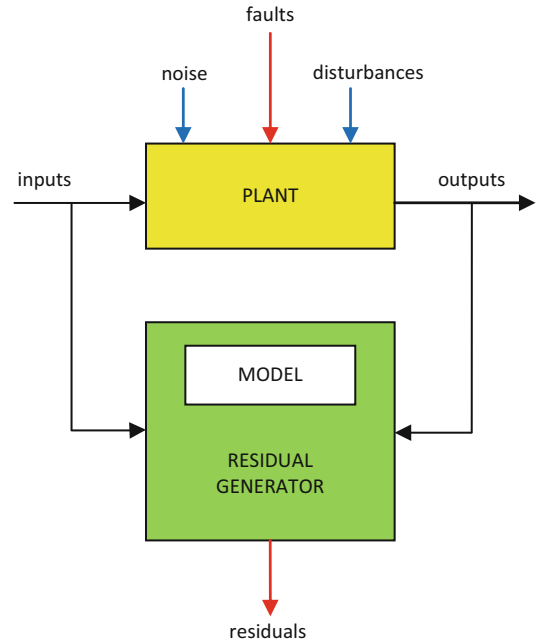
The ("primary") residual vector $\mathbf{e}(t)$, in response to additive faults, is

$$\mathbf{e}(t) = \mathbf{y}(t) - \mathbf{M}(q, \boldsymbol{\theta})\mathbf{u}(t) = \mathbf{S}(q, \boldsymbol{\theta})\mathbf{p}(t)$$

If there are multiplicative faults, then $\boldsymbol{\theta} = \boldsymbol{\theta}^{\circ} + \boldsymbol{\Delta\theta}$, where $\boldsymbol{\theta}^{\circ}$ is the nominal parameter vector and $\boldsymbol{\Delta\theta}$ is its change (the parametric fault); now and the residual vector $\mathbf{e}(t)$ is (Gertler 1998)

$$\begin{aligned}\mathbf{e}(t) &= \mathbf{y}(t) - \mathbf{M}(q, \boldsymbol{\theta}^{\circ})\mathbf{u}(t) \\ &= \Sigma_j(\partial\mathbf{M}(q, \boldsymbol{\theta})/\partial\theta_j)\mathbf{u}(t)\,\Delta\theta_j\end{aligned}$$

Enhanced residuals. To facilitate the isolation of faults, the primary residuals $\mathbf{e}(t)$ are subject to some enhancement manipulation. The three widely used enhancement techniques are:

– *Structured residuals*, whereas each residual is selectively sensitive to a subset of faults, resulting in a fault-specific set of zero/nonzero residuals upon a particular fault (fault codes)


Fault Detection and Diagnosis, Fig. 2 Generating model-based residuals

– *Directional residuals*, whereas the residual vector maintains a fault-specific direction in response to each particular fault
– *Diagonal residuals*, whereas each residual responds only to a particular fault

Residual generators take the input and output observations from the plant and generate enhanced residuals by one of the above schemes, utilizing the mathematical model of the plant (Fig. 2).

Dealing with noise. Noise is practically unavoidable in physical systems. In FDD, basically two steps may be taken to reduce the effect of noise:

– *Residual filtering*. This can be achieved by basing decisions on moving averages of the residuals or by applying explicit low-pass filters to the residuals or by designing the residual generators in such a way that they have built-in low-pass behavior.
– *Statistical testing of the residuals*. Structured residuals are tested individually; each scalar residual is then represented by a Boolean 1 or 0, depending on the outcome of the

test. Directional residuals are tested as vectors against multivariable distributions. The test thresholds are determined either theoretically, using assumptions for the source noise, or empirically based on measurements from fault-free operating conditions.

Dealing with disturbances. Additive disturbances are unmeasurable inputs. If the disturbance-to-output transfer function (or equivalent state-space representation) is known, then it is possible to design residuals that are completely decoupled from (insensitive to) those disturbances. However, the FDD algorithm is subject to a certain degree of "design freedom," defined by the number of outputs in the physical system; disturbance decoupling is competing for this freedom with fault isolation enhancement. If there are too many disturbances, or if their path to the outputs is unknown, then only approximate decoupling is possible, making FDD also approximate, usually designed to optimize some (H-infinity) performance index.

Dealing with model errors. Model errors are also unavoidable in most practical situations. This is the most serious obstacle in the application of model-based FDD techniques. In some very special cases, uncertainty of a particular plant parameter may be handled as a "multiplicative disturbance," and residuals designed to be explicitly decoupled from it. In general, however, only approximate solutions are possible, reducing the residuals' sensitivity to modeling errors, at the expense of also reducing their sensitivity to faults. Design methods utilizing some optimization techniques, mostly based on H-infinity or similar performance indices, are available in the literature (Edelmayer et al. 1994).

Residual Generation Methods

For linear dynamic systems, provided exact (non-approximate) solution is possible, there are three major techniques to design residual generators: (i) direct consistency (parity) relations, (ii) parity space, and (iii) diagnostic observers. We will briefly introduce the three methods, for discrete-time plant models and additive faults. Note that though they look formally different, if designed for the same plant under the same design conditions, the three methods yield identical residuals (Gertler 1991).

Direct consistency (parity) relations (Gertler 1998)**.** The input-output model of the plant is utilized directly in the design. The enhanced residuals are obtained from the primary residuals by a transformation $\mathbf{W}(q)$:

$$\begin{aligned} \mathbf{r}(t) &= \mathbf{W}(q)\mathbf{e}(t) = \mathbf{W}(q)[\mathbf{y}(t) - \mathbf{M}(q)\mathbf{u}(t)] \\ &= \mathbf{W}(q)\mathbf{S}(q)\mathbf{p}(t) \end{aligned}$$

The desired behavior of the residuals is specified as $\mathbf{r}(t) = \mathbf{Z}(q)\mathbf{p}(t)$, where the specification $\mathbf{Z}(q)$ contains the basic residual properties (structure or directions) plus the residual dynamics. The resulting design condition is $\mathbf{W}(q)\mathbf{S}(q) = \mathbf{Z}(q)$. If the $\mathbf{S}(q)$ matrix is square, what is usually the case (Gertler 1998), then this can be solved for $\mathbf{W}(q)$ by direct inversion. The residual generator has to be causal and stable; this can always be achieved by the appropriate modification of the dynamics in $\mathbf{Z}(q)$.

Parity space (Chow and Willsky 1984). This method, also known as the "Chow-Willsky scheme," relies on the state-space description of the system:

$$\begin{aligned} \mathbf{x}(t+1) &= \mathbf{A}\,\mathbf{x}(t) + \mathbf{B}\,\mathbf{u}(t) + \mathbf{E}\,\mathbf{p}(t) \\ \mathbf{y}(t) &= \mathbf{C}\,\mathbf{x}(t) + \mathbf{D}\,\mathbf{u}(t) + \mathbf{F}\,\mathbf{p}(t) \end{aligned}$$

Stacking n consecutive output vectors $\mathbf{y}(t)$ (where n is the order of the model), and chain-substituting the state $\mathbf{x}(t)$, yields the equation

$$\mathbf{Y}(t) = \mathbf{J}\,\mathbf{x}(t-n) + \mathbf{K}\,\mathbf{U}(t) + \mathbf{L}\,\mathbf{P}(t)$$

where $\mathbf{Y}(t), \mathbf{U}(t)$, and $\mathbf{P}(t)$ are stacked vectors and $\mathbf{J}, \mathbf{K}$, and $\mathbf{L}$ are hyper-matrices composed of the $\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D}, \mathbf{E}, \mathbf{F}$ matrices. Now

$$\mathbf{E}^*(t) = \mathbf{Y}(t) - \mathbf{K}\,\mathbf{U}(t) = \mathbf{L}\,\mathbf{P}(t) + \mathbf{J}\,\mathbf{x}(t-n)$$

would be a stacked vector of primary residuals, was it not for the presence of the inaccessible initial state $\mathbf{x}(t-n)$. To obtain true residuals, a transformation $r_i(t) = \mathbf{w}_i \mathbf{E}^*(t)$ is necessary, so that $\mathbf{w}_i \mathbf{J} = 0$. Any vector $\mathbf{w}_i$ satisfying this orthogonality condition is a *parity vector*, together spanning the *parity space*. Any parity vector yields a true residual $r_i(t)$; they can be so chosen that a set of residuals possesses structured behavior.

Diagnostic observers. Various observer schemes have been extensively investigated as possible residual generator algorithms. The basic full-order *Luenberger observer* (assuming $\mathbf{D} = \mathbf{0}$) is

$$\mathbf{x}^{(t+1)} = \mathbf{A}\,\mathbf{x}^{(t)} + \mathbf{B}\,\mathbf{u}(t) + \mathbf{K}\,\mathbf{e}(t)$$

where $\mathbf{K}$ is the observer gain matrix and

$$\mathbf{e}(t) = \mathbf{y}(t) - \mathbf{C}\,\mathbf{x}^{(t)}$$

is the innovation vector. If the observer is stable then, apart from the start-up transient of the observer, the innovation qualifies as the primary residual. The gain matrix $\mathbf{K}$ is the major design parameter; it is chosen to place the observer poles, thus achieving stability and desired dynamic behavior (e.g., noise suppression). The remaining design freedom can be utilized to influence residual properties. The latter are further affected by the transformation $\mathbf{r}(t) = \mathbf{H}\,\mathbf{e}(t)$, where the $\mathbf{H}$ matrix is an additional design parameter. Diagnostic observers can be designed for both structured and directional residuals (Chen and Patton 1999; White and Speyer 1987). Other observer schemes, most notably the *unknown input observer*, have also been proposed (Frank and Wunnenberg 1989). Because of their complexity, the detailed design procedures of diagnostic observers go beyond the scope of this entry.

Principal Component Analysis

Principal component analysis is extensively used in the monitoring of complex plants with hundreds of variables because, by revealing linear relations among the variables, it significantly reduces the dimensionality of the plant model (Kresta et al. 1991). The application of PCA for FDD implies two phases. In the training phase, an implicit plant model is created from empirical plant data. In the monitoring phase, this model is used for FDD.

Training data (measured inputs and outputs) are collected from the plant during fault-free operation. The covariance matrix of the data is formed and its eigenstructure obtained. Due to linear relations among the data, some of the eigenvalues will be zero (or near zero, in the presence of noise). The eigenvectors belonging to the nonzero eigenvalues form the *data space*, where the fault-free data exist, while those belonging to the zero eigenvalues form the *residual space*.

It is the residual space that is utilized for FDD. The projection of a measurement vector onto the residual space is the (primary) residual. A statistical test on its size leads to a detection decision (the absence or presence of faults). A threshold test is necessary because noise also causes nonzero residuals. An analysis of the eigenvectors spanning the residual space shows how the various faults propagate to the primary residual. This allows for the design of residual manipulations yielding structured or directional residuals, just like in the FDD methods based on exact models (Gertler et al. 1999).

The procedure as described above applies to sensor and actuator faults; inclusion of plant faults requires extra effort (and experiments). Also, PCA is primarily meant for static models. Its extension to discrete-time dynamic models is straightforward, but it increases the size of the model, proportionally to the dynamic order of the model.

Summary and Future Directions

Fault detection and diagnosis is today a mature field of systems and control engineering. There is a very significant level of activity, as measured in published papers and conference contributions, but much of this (in the opinion of this author)

is just minor refinements of earlier results. This applies particularly to the long ongoing quest to create "robust" FDD algorithms, especially in the face of model errors.

There are still open challenges in a couple of areas, most notably extensions to various nonlinear or parameter varying problems. Another open and active area, of great practical importance, is FDD in networked control systems. What is really of the greatest interest, though, is the application of the wealth of available theoretical results and design methods to real-life problems; there has recently been some visible progress here, a most welcome development.

FTC

Abstract

A closed-loop control system for an engineering process may have unsatisfactory performance or even instability when faults occur in actuators, sensors, or other process components. Fault-tolerant control (FTC) involves the development and design of special controllers that are capable of tolerating the actuator, sensor, and process faults while still maintaining desirable and robust performance and stability properties. FTC designs involve knowledge of the nature and/or occurrence of faults in the closed-loop system either implicitly or explicitly using methods of fault detection and isolation (FDI), fault detection and diagnosis (FDD), or fault estimation (FE). FTC controllers are reconfigured or restructured using FDI/FDD information so that the effects of the faults are reduced or eliminated within each feedback loop in *active* or *passive* approaches or compensated in each control-loop using FE methods. A non-mathematical outline of the essential features of FTC systems is given with important definitions and a classification of FTC systems

into either active/passive approaches with examples of some well-known strategies.

Keywords

Active FTC; Fault accommodation; Fault detection and diagnosis (FDD); Fault detection and isolation (FDI); Fault estimation (FE); Fault-tolerant control; Passive FTC; Reconfigurable control

Introduction

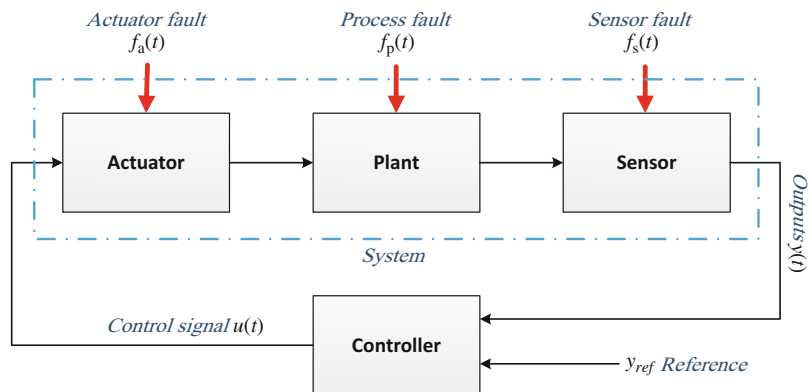
The complexity of modern engineering systems has led to strong demands for enhanced control system reliability, safety, and green operation in the presence of even minor anomalies. There is a growing need not only to determine the onset and development of process faults before they become serious but also to adaptively compensate for their effects in the closed-loop system or using hardware redundancy to replace faulty components by duplicate and fault-free alternatives. The title "failure tolerant control" was given by Eterno et al. (1985) working on a reconfigurable flight control study defining the meaning of control system tolerance to failures or faults. The word "failure" is used when a fault is so serious that the system function concerned fails to operate (Isermann 2006). The title failure detection has now been superseded by *fault detection*, e.g., in *fault detection and isolation* (FDI) or *fault detection and diagnosis* (FDD) (Chen and

Patton 1999; Gertler 1998; Patton et al. 2000) motivated by studies in the 1980s on this topic (Patton et al. 1989). *Fault-tolerant control* (FTC) began to develop in the early 1990s (Patton 1993) and is now a standard in the literature (Patton 1997; Blanke et al. 2006; Zhang and Jiang 2008), based on the aerospace subject of reconfigurable flight control making use of redundant actuators and sensors (Steinberg 2005; Edwards et al. 2010).

Definitions Relating to Fault-Tolerant Control

FTC is a strategy in control systems architecture and design to ensure that a closed-loop system can continue acceptable operation in the face of bounded actuator, sensor, or process faults. The goal of FTC design must ensure that the closed-loop system maintains satisfactory stability and acceptable performance during either one or more fault actions. When prescribed stability and closed-loop performance indices are maintained despite the action of faults, the system is said to be "fault tolerant," and the control scheme that ensures the fault tolerance is the fault-tolerant controller (Blanke et al. 2006; Patton 1997).

Fault modelling is concerned with the representation of the real physical faults and their effects on the system mathematical model. Fault modelling is important to establish how a fault should be detected, isolated, or compensated.

Fault-Tolerant Control, Fig. 1 Closed-loop system with actuator, process, and sensor faults


The faults illustrated in Fig. 1 act at system locations defined as follows (Chen and Patton 1999):

An ***actuator fault*** ($f_a(t)$) corresponds to variations of the control input $u(t)$ applied to the controlled system either completely or partially. The complete failure of an actuator means that it produces no actuation regardless of the input applied to it, e.g., as a result of breakage and burnout of wiring. For partial actuator faults, the actuator becomes less effective and provides the plant with only a part of the normal actuation signal.

A sensor is an item of equipment that takes a measurement or observation from the system, e.g., potentiometers, accelerometers, tachometers, pressure gauges, strain gauges, etc.; a ***sensor fault*** ($f_s(t)$) implies that incorrect measurements are taken from the real system. This fault can also be subdivided into either a complete or partial sensor fault. When a sensor fails, the measurements no longer correspond to the required physical parameters. For a partial sensor fault the measurements give an inaccurate indication of required physical parameters.

A ***process fault*** ($f_p(t)$) directly affects the physical system parameters and in turn the input/output properties of the system. Process faults are often termed *component faults*, arising as variations from the structure or parameters used during system modelling, and as such cover a wide class of possible faults, e.g., dirty water having a different heat transfer coefficient compared to when it is clean, or changes in the viscosity of a liquid or components slowly degrading over time through wear and tear, aging, or environmental effects.

Architectures and Classification of FTC Schemes

FTC methods are classified according to whether they are "passive" or "active," using fixed or reconfigurable control strategies (Eterno et al. 1985). Various architectures have been proposed for the implementation of FTC schemes, for example, the structure of reconfigurable control

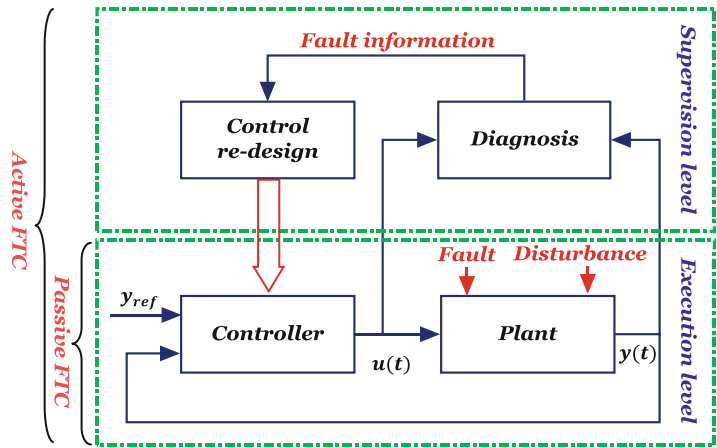
based on generalized internal model control (GIMC) has been proposed by Zhou and Ren (2001) and other studies by Niemann and Stoustrup (2005). Figure 2 shows a suitable architecture to encompass active and passive FTC methods in which a distinction is made between "execution" and "supervision" levels. The essential differences and requirements between the passive FTC (PFTC) and active FTC (AFTC).

PFTC is based solely on the use of robust control in which potential faults are considered as if they are uncertain signals acting in the closed-loop system. This can be related to the concept of reliable control (Veillette et al. 1992). PFTC requires no online information from the fault diagnosis (FDI/FDD/FE) function about the occurrence or presence of faults and hence it is not by itself and adaptive system and does not involve controller reconfiguration (Patton 1993, 1997; Šiljak 1980). PFTC approach can be used if the time window during which the system remains stabilizable in the presence of a fault is short; see, for example, the problem of the double inverted pendulum (Weng et al. 2007) which is unstable during a loop failure.

AFTC has *two* conceptual steps to provide the system with fault-tolerant capability (Blanke et al. 2006; Patton 1997; Zhang and Jiang 2008; Edwards et al. 2009):

- Equip the system with a mechanism to make it able to detect and isolate (or even estimate) the fault promptly, identify a faulty component, and select the required remedial action in to maintain acceptable operation performance. With no fault a *baseline controller* attenuates disturbances and ensures good stability and closed-loop tracking performance (Patton 1997), and the diagnostic (FDI/FDD/FE) block recognizes that the closed-loop system is fault-free with no control law change required (supervision level).
- Make use of supervision level information and adapt or reconfigure/restructure the controller parameters so that the required remedial activity can be achieved (execution level).

Figure 3 gives a classification of PFTC and AFTC methods (Patton 1997).

Fault-Tolerant Control, Fig. 2 Scheme of FTC (Adapted from Blanke et al. (2006))


**Fault-Tolerant Control, Fig. 3** General classification of FTC methods

F

Figure 3 shows that AFTC approaches are divided into two main types of methods: projection-based methods and online automatic controller redesign methods. The latter involves the calculation of new controller parameters following control impairment, i.e., using reconfigurable control. In projection-based methods, a new precomputed control law is selected according to the required controller structure (i.e., depending on the type of isolated fault).

AFTC methods use online-fault accommodation based on unanticipated faults, classified as (Patton 1997):

(a) Based on offline (pre-computed) control laws
(b) Online-fault accommodating

(c) Tolerant to unanticipated faults using FDI/FDD/FE
(d) Dependent upon use of a baseline controller

AFTC Examples

One example of AFTC is model-based predictive control (MPC) which uses online computed control redesign. MPC is online-fault accommodating; it does not use an FDI/FDD unit and is not dependent on a baseline controller. MPC has a certain degree of fault tolerance against actuator faults under some conditions even if the faults are not detected. The representation of actuator faults in MPC is relatively natural and straightforward since actuator faults such as jams and slew-rate reductions can be represented by changing the

MPC optimization problem constraints. Other faults can be represented by modifying the internal model used by MPC (Maciejowski 1998). The fact that online-fault information is not required means that MPC is an interesting method for flight control reconfiguration as demonstrated by Maciejowski and Jones in the GARTEUR AG 16 project on "fault-tolerant flight control" (Edwards et al. 2010).

Another interesting AFTC example that makes use of the concept of *model-matching* in explicit model following is the so-called pseudo-inverse method (PIM) (Gao and Antsaklis 1992) which requires the nominal or reference closed-loop system matrix to compute the new controller gain after a fault has occurred. The challenges are:

1. Guarantee of stability of the reconfigured closed-loop system
2. Minimization of the time consumed to approach the acceptable matching
3. Achieving perfect matching through use of different control methodologies

Exact model-matching may be too demanding, and some extensions to this approach make use of alternative, approximate (norm-based) model-matching through the computation of the required model-following gain. To relax the matching condition further, Staroswiecki (2005) proposed an *admissible model-matching* approach which was later extended by Tornil et al. (2010) using D-region pole assignment. The PIM approach requires an FDI/FDD/FE mechanism and is online-fault accommodating only in terms of *a priori* anticipated faults. This limits the practical value of this approach.

As a third example, feedback linearization can be used to compensate for nonlinear dynamic effects while also implementing control law reconfiguration or restructure. In flight control an aileron actuator fault will cause a strong coupling between the lateral and longitudinal aircraft dynamics. Feedback linearization is an established technique in flight control (Ochi and Kanai 1991). The faults are identified indirectly by estimating aircraft flight parameters online, e.g., using a recursive least-squares algorithm to update the FTC.

Hence, a AFTC system provides fault tolerance either by selecting a precomputed control law (*projection-based*) (Boskovic and Mehra 1999; Maybeck and Stevens 1991; Rauch 1995) or by synthesizing a new control strategy online (*online controller redesign*) (Ahmed-Zaid et al. 1991; Richter et al. 2007; Efimov et al. 2012; Zou and Kumar 2011).

Another widely studied AFTC method is the *estimation and compensation approach*, where a fault compensation input is superimposed on the nominal control input (Noura et al. 2000; Boskovic and Mehra 2002; Sami and Patton 2013; Zhang et al. 2004). There is a growing interest in robust FE methods based on sliding mode estimation (Edwards et al. 2000) and augmented observer methods (Gao and Ding 2007; Jiang et al. 2006; Sami and Patton 2013).

An important development of this approach is the so-called fault hiding strategy which is centered on achieving FTC loop goals such that the nominal control loop remains unchanged through the use of virtual actuators or virtual sensors (Blanke et al. 2006; Sami and Patton 2013). Fault hiding makes use of the difference between the nominal and faulty system state to changes in the system dynamics such that the required control objectives are continuously achieved even if a fault occurs. In the sensor fault case, the effect of the fault is hidden from the input of the controller. However, actuator faults are compensated by the effect of the fault (Lunze and Steffen 2006; Richter et al. 2007; Ponsart et al. 2010; Sami and Patton 2013) in which it is assumed that the FDI/FDD or FE scheme is available. The virtual actuator/sensor FTC can be good practical value if FDI/FDD/FE robustness can be demonstrated.

Traditional adaptive control methods that automatically adapt controller parameters to system changes can be used in a special application of AFTC, potentially removing the need for FDI/FDD and controller redesign steps (Tang et al. 2004; Zou and Kumar 2011) but possibly using the FE function. Adaptive control is suitable for FTC on plants that have slowly

varying parameters and can tolerate actuator and process faults. Sensor faults are not tolerated well as the controller parameters must adapt according to the faulty measurements, causing incorrect closed-loop system operation; the FDI/FDD/FE unit is required for such cases.

Summary and Future Directions

FTC is now a significant subject in control systems science with many quite significant application studies, particularly since the new millennium. Most of the applications are within the flight control field with studies such as the GARTEUR AG16 project "Fault-Tolerant Flight Control" (Edwards et al. 2010). As a very complex engineering-led and mathematically focused subject, it is important that FTC remains application-driven to keep the theoretical concepts moving in the right directions and satisfying end-user needs. The original requirement for FTC in safety-critical systems has now widened to encompass a good range of fault-tolerance requirements involving energy and economy, e.g., for greener aircraft and for FTC in renewable energy.

Faults and modelling uncertainties as well as endogenous disturbances have potentially competing effects on the control system performance and stability. This is the *robustness problem in FTC* which is beyond the scope of this article. The FTC system provides a degree of tolerance to closed-loop systems faults and it is also subject to the effects of modelling uncertainty arising from the reality that all engineering systems are nonlinear and can even have complex dynamics. For example, consider the PFTC approach relying on robustness principles – as a more complex extension to robust control. PFTC design requires the closed-loop system to be insensitive to faults as well as modelling uncertainties. This requires the use of multi-objective optimization methods e.g., using linear matrix inequalities (LMI), as well as methods of accounting for dynamical system parametric variations, e.g., linear parameter varying (LPV) system structures, Takagi-Sugeno, or sliding mode methods.

Feedback Linearization of Nonlinear Systems

A.J. Krener
Department of Applied Mathematics, Naval Postgrauate School, Monterey, CA, USA

Abstract

Effective methods exist for the control of linear systems but this is less true for nonlinear systems. Therefore, it is very useful if a nonlinear system can be transformed into or approximated by a linear system. Linearity is not invariant under nonlinear changes of state coordinates and nonlinear state feedback. Therefore, it may be possible to convert a nonlinear system into a linear one via these transformations. This is called feedback

linearization. This entry surveys feedback linearization and related topics.

Keywords

Distribution; Frobenius theorem; Involutive distribution; Lie derivative

Introduction

A controlled linear dynamics is of the form

$$\dot{x} = Fx + Gu \qquad (1)$$

where the state $x \in I\!\!R^n$ and the control $u \in I\!\!R^m$. A controlled nonlinear dynamics is of the form

$$\dot{x} = f(x, u) \qquad (2)$$

where x, u have the same dimensions but may be local coordinates on some manifolds $\mathcal{X}$, $\mathcal{U}$. Frequently, the dynamics is affine in the control, i.e.,

$$\dot{x} = f(x) + g(x)u \qquad (3)$$

where $f(x) \in I\!\!R^{n \times 1}$ is a vector field and $g(x) = [g^1(x), \dots, g^m(x)] \in I\!\!R^{n \times m}$ is a matrix field.

Linear dynamics are much easier to analyze and control than nonlinear dynamics. For example, to globally stabilize the linear dynamics (1), all we need to do is to find a linear feedback law $u = Kx$ such that all the eigenvalues of $F + GK$ are in the open left half plane. Finding a feedback law $u = \kappa(x)$ to globally stabilize the nonlinear dynamics is very difficult and frequently impossible. Therefore, finding techniques to linearize nonlinear dynamics has been a goal for several centuries.

The simplest example of a linearization technique is to approximate a nonlinear dynamics around a critical point by its first-order terms. Suppose x^0, u^0 is an operating point for the nonlinear dynamics (2), that is, $f(x^0, u^0) = 0$. Define displacement variables $z = x - x^0$ and $v = u - u^0$, and assuming $f(x, u)$ is smooth

around this operating point, expand (2) to first order

$$\dot{z} = \frac{\partial f}{\partial x}(x^0, u^0)z + \frac{\partial f}{\partial u}(x^0, u^0)v$$
$$+ O(z, v)^2 \qquad (4)$$

Ignoring the higher order terms, we get a linear dynamics (1) where

$$F = \frac{\partial f}{\partial x}(x^0, u^0), \quad G = \frac{\partial f}{\partial u}(x^0, u^0)$$

This simple technique works very well in many cases and is the basis for many engineering designs. For example, if the linear feedback $v = Kz$ puts all the eigenvalues of $F + GK$ in the left half plane, then the affine feedback $u = u^0 + K(x - x^0)$ makes the closed-loop dynamics locally asymptotically stable around x^0. So, one way to linearize a nonlinear dynamics is to approximate it by a linear dynamics.

The other way to linearize is by a nonlinear change of state coordinates and a nonlinear state feedback because linearity is not invariant under these transformations. To see this, suppose we have a controlled linear dynamics (1) and we make the nonlinear change of state coordinates $z = \phi(x)$ and nonlinear feedback $u = \gamma(z, v)$. We assume that these transformations are invertible from some neighborhood of $x^0 = 0, u^0 = 0$ to some neighborhood of z^0, v^0, and the inverse maps are

$$\psi(\phi(x)) = x, \quad \phi(\psi(z) = z$$
$$\kappa(\psi(z), \gamma(z, v)) = v, \quad \gamma(\phi(x), \kappa(x, u)) = u$$

then (1) becomes

$$\dot{z} = \frac{\partial \phi}{\partial x}(x)(Fx + Gu)$$
$$= \frac{\partial \phi}{\partial x}(\psi(z))(F\psi(z) + G\gamma(z, v))$$

which is a controlled nonlinear dynamics (2). This raises the question asked by Brockett (1978), when is a controlled nonlinear dynamics a change of coordinate and feedback away from a controlled linear dynamics?

F

Linearization of a Smooth Vector Field

Let us start by addressing an apparently simpler question that was first considered by Poincaré. Given an uncontrolled nonlinear dynamics around a critical point, say $x^0 = 0$,

$$\dot{x} = f(x), \qquad f(0) = 0,$$

find a smooth local change of coordinates

$$z = \phi(x), \quad \phi(0) = 0$$

which transforms it into an uncontrolled linear dynamics.

$$\dot{z} = Fz.$$

This question is apparently simpler, but as we shall see in the next section, the corresponding question for a controlled nonlinear dynamics that is affine in the control is actually easier to answer.

Without loss of generality, we can restrict our attention to changes of coordinates which carry $x^0 = 0$ to $z^0 = 0$ and whose Jacobian at this point is the identity, i.e.,

$$z = x + O(x^2)$$

then

$$F = \frac{\partial f}{\partial x}(0).$$

Poincaré's formal solution to this problem was to expand the vector field and the desired change of coordinates in a power series,

$$\dot{x} = Fx + f^{[2]}(x) + O(x^3)$$
$$z = x - \phi^{[2]}(x)$$

where $f^{[2]}$, $\phi^{[2]}$ are n-dimensional vector fields, whose entries are homogeneous polynomials of degree 2 in x. A straightforward calculation yields

$$\dot{z} = Fz + f^{[2]}(x) - \left[Fx, \phi^{[2]}(x)\right] + O(x)^3$$

where the Lie bracket of two vector fields $f(x)$, $g(x)$ is the new vector field defined by

$$[f(x), g(x)] = \frac{\partial g}{\partial x}(x)f(x) - \frac{\partial f}{\partial x}(x)g(x).$$

Hence, $\phi^{[2]}(x)$ must satisfy the so-called homological equation (Arnol'd 1983)

$$\left[Fx, \phi^{[2]}(x)\right] = f^{[2]}(x).$$

This is a linear equation from the space of quadratic vector fields to the space of quadratic vector fields. The quadratic n-dimensional vector fields form a vector space of dimension n times $n + 1$ choose 2.

Poincaré showed that the eigenvalues of the linear map

$$\phi^{[2]}(x) \mapsto \left[Fx, \phi^{[2]}(x)\right] \tag{5}$$

are $\lambda_i + \lambda_j - \lambda_k$ where $\lambda_i, \lambda_j, \lambda_k$ are eigenvalues of F. If none of these expressions are zero, then the operator (5) is invertible. A degree two resonance occurs when $\lambda_i + \lambda_j - \lambda_k = 0$ and then the homological equation is not solvable for all $f^{[2]}(x)$.

Suppose a change of coordinates exists that linearizes the vector field up to degree r. In the new coordinates, the vector field is of the form

$$\dot{x} = Fx + f^{[r]}(x) + O(x)^{r+1}.$$

We seek a change of coordinates of the form

$$z = x - \phi^{[r]}(x)$$

to cancel the degree r terms, i.e., we seek a solution of the rth degree homological equation,

$$\left[Fx, \phi^{[r]}(x)\right] = f^{[r]}(x).$$

A degree r resonance occurs if

$$\lambda_{i_1} + \ldots + \lambda_{i_r} - \lambda_k = 0.$$

If there is no resonance of degree r, then the degree r homological equation is uniquely solvable for every $f^{[r]}(x)$.

When there are no resonances of any degree, then the convergence of the formal power series solution is delicate. We refer the reader to Arnol'd (1983) for the details.

Linearization of a Controlled Dynamics by Change of State Coordinates

Given a controlled affine dynamics (3) when does there exist a smooth local change of coordinates

$$z = \phi(x), \qquad 0 = \phi(0)$$

transforming it to

$$\dot{z} = Fz + Gu$$

where

$$F = \frac{\partial f}{\partial x}(0), \qquad G = g(0)$$

This is an easier question to answer than that of Poincaré.

The controlled affine dynamics (3) is said to have well-defined controllability (Kronecker) indices if there exists a reordering of $g^1(x), \ldots, g^m(x)$ and integers $r_1 \geq r_2 \geq \cdots \geq r_m \geq 0$ such that $r_1 + \cdots + r_m = n$, and the vector fields

$$\{ad^k(f)g^j : j = 1, \ldots, m, \ k = 0, \ldots, r_j - 1\}$$

are linearly independent at each x where g^i denotes the ith column of g and

$$ad^0(f)g^i = g^i, \ \ ad^k(f)g^i = \left[f, ad^{k-1}(f)g^i\right].$$

If there are several sets of indices that satisfy this definition, then the controllability indices are the smallest in the lexicographic ordering.

A necessary and sufficient condition is that

$$\left[ad^k(f)g^i, ad^l(f)g^j\right] = 0$$

for $k = 0, \ldots, n-1, \ l = 0, \ldots, n$

The proof of this theorem is straightforward. Under a change of state coordinates, the vector fields and their Lie brackets are transformed by the Jacobian of the coordinate change. Trivially for linear systems,

$$ad^k(Fx)G^i = (-1)^k F^k G$$
$$\left[ad^k(Fx)G^i, ad^l(Fx)G^j\right] = 0.$$

Feedback Linearization

We turn to a question posed and partially answered by Brockett (1978). Given a system affine in the m-dimensional control

$$\dot{x} = f(x) + g(x)u,$$

find a smooth local change of coordinates and smooth feedback

$$z = \phi(x), \quad u = \alpha(x) + \beta(x)v$$

transforming it to

$$\dot{z} = Fz + Gv$$

Brockett solved this problem under the assumptions that β is a constant and the control is a scalar, $m = 1$. The more general question for $\beta(x)$ and arbitrary m was solved in different ways by Korobov (1979), Jakubczyk and Respondek (1980), Sommer (1980), Hunt and Su (1981), Su (1982), and Hunt et al. (1983).

We describe the solution when $m = 1$. If the pair F, G is controllable, then there exist an H such that

$$HF^{k-1}G = 0 \qquad k = 1, \ldots, n-1$$
$$HF^{n-1}G = 1$$

If the nonlinear system is feedback linearizable, then there exists a function $h(x) = H\phi(x)$ such that

$$L_{ad^{k-1}(f)g}h = 0 \qquad k = 1, \ldots, n-1$$

$$L_{ad^{n-1}(f)g}h \neq 0$$

where the Lie derivative of a function h by a vector field g is given by

$$L_g h = \frac{\partial h}{\partial x}g$$

This is a system of first-order PDEs, and the solvability conditions are given by the classical Frobenius theorem, namely, that

$$\{g, \ldots, ad^{n-2}(f)g\}$$

is involutive, i.e., its span is closed under Lie bracket.

For controllable systems, this is a necessary and sufficient condition. The controllability condition is that $\{g, \ldots, ad^{n-1}(f)g\}$ spans x space.

Suppose $m = 2$ and the system has controllability (Kronecker) indices $r_1 \geq r_2$. Such a system is feedback linearizable iff

$$\{g^1, , g^2, \ldots, ad^{r_i-2}(f)g^1, ad^{r_i-2}(f)g^2\}$$

is involutive for $i = 1, 2$. Another way of putting is that the distribution spanned by the first through rth rows of the following matrix must be involutive for $r = r_i - 1$, $i = 1, 2$. This is equivalent to the distribution spanned by the first through rth rows of the following matrix being involutive for all $r = 1, \ldots, r_1$.

$$\begin{bmatrix} g^1 & g^2 \\ ad(f)g & ad(f)g^2 \\ \vdots & \vdots \\ ad^{r_2-2}(f)g^1 & ad^{r_2-2}(f)g^2 \\ ad^{r_2-1}(f)g^1 & ad^{r_2-1}(f)g^2 \\ \vdots & \\ ad^{r_1-2}(f)g^1 & \\ ad^{r_1-1}(f)g^1 & \end{bmatrix}$$

One might ask if it is possible to use dynamic feedback to linearize a system that is not linearizable by static feedback. Suppose we treat one of the controls u_j as a state and let its derivative be a new control,

$$\dot{u}_j = \bar{u}_j$$

can the resulting system be linearized by state feedback and change of state coordinates? Loosely speaking, the effect of adding such an integrator to the jth control is to shift the jth column of the above matrix down by one row. This changes the distribution spanned by the first through rth rows of the above matrix and might make it involutive. A scalar input system $m = 1$ that is linearizable by dynamic state feedback is also linearizable by static state feedback. There are multi-input systems $m > 1$ that are dynamically linearizable but not statically linearizable (Charlet et al. 1989, 1991).

The generic system is not feedback linearizable, but mechanical systems with one actuator for each degree of freedom typically are feedback linearizable. This fact had been used in many applications, e.g., robotics, before the concept of feedback linearization.

One should not lose sight of the fact that stabilization, model-matching, or some other performance criterion is typically the goal of controller design. Linearization is a means to the goal. We linearize because we know how to meet the performance goal for linear systems.

Even when the system is linearizable, finding the linearizing coordinates and feedback can be a nontrivial task. Mechanical systems are the exception as the linearizing coordinates are usually the generalized positions. Since the $ad^{k-1}(f)g$ for $k = 1, \ldots, n-1$ are characteristic directions of the PDE for h, the general solutions of the ODE's

$$\dot{x} = ad^{k-1}(f)g(x)$$

can be used to construct the solution (Blankenship and Quadrat 1984). The Gardner-Shadwick (GS) algorithm (1992) is the most efficient method that is known.

Linearization of discrete time systems was treated by Lee et al. (1986). Linearization of discrete time systems around an equilibrium

manifold was treated by Barbot et al. (1995) and Jakubczyk (1987). Banaszuk and Hauser have also considered the feedback linearization of the transverse dynamics along a periodic orbit, (Banaszuk and Hauser 1995a,b).

Input–Output Linearization

Feedback linearization as presented above ignores the output of the system but typically one uses the input to control the output. Therefore, one wants to linearize the input–output response of the system rather than the dynamics. This was first treated in Isidori and Krener (1982) and Isidori and Ruberti (1984).

Consider a scalar input, scalar output system of the form

$$\dot{x} = f(x) + g(x)u, \qquad y = h(x)$$

The relative degree of the system is the number of integrators between the input and the output. To be more precise, the system is of relative degree $r \geq 1$ if for all x of interest,

$$L_{ad^j(f)g}h(x) = 0 \qquad j = 0, \ldots, r-2$$
$$L_{ad^{r-1}(f)g}h(x) \neq 0$$

In other words, the control appears first in the rth time derivative of the output. Of course, a system might not have a well-defined relative degree as the r might vary with x.

Rephrasing the result of the previous section, a scalar input nonlinear system is feedback linearizable if there exist an pseudo-output map $h(x)$ such the resulting scalar input, scalar output system has a relative degree equal to the state dimension n.

Assume we have a scalar input, scalar output system with a well-defined relative degree $1 \leq r \leq n$. We can define r partial coordinate functions

$$\zeta_i(x) = (L_f)^{i-1}h(x) \qquad i = 1, \ldots, r$$

and choose $n - r$ functions $\xi_i(x), i = 1, \ldots, n-r$ so that (ζ, ξ) are a full set of coordinates on the state space. Furthermore, it is always possible (Isidori 1995) to choose $\xi_i(x)$ so that

$$L_g\xi_i(x) = 0 \qquad i = 1, \ldots, n-r$$

In these coordinates, the system is in the normal form

$$y = \zeta_1$$
$$\dot{\zeta}_1 = \zeta_2$$
$$\vdots$$
$$\dot{\zeta}_{r-1} = \zeta_r$$
$$\dot{\zeta}_r = f_r(\zeta, \xi) + g_r(\zeta, \xi)u$$
$$\dot{\xi} = \phi(\zeta, \xi)$$

The feedback $u = u(\zeta, \xi, v)$ defined by

$$u = \frac{(v - f_r(\zeta, \xi))}{g_r(\zeta, \xi)}$$

transforms the system to

$$y = H\zeta$$
$$\dot{\zeta} = F\zeta + Gv$$
$$\dot{\xi} = \phi(\zeta, \xi)$$

where F, G, H are the $r \times r$, $r \times 1$, $1 \times r$ matrices

$$F = \begin{bmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & 1 \\ 0 & 0 & 0 & \ldots & 0 \end{bmatrix} \qquad G = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

$$H = \begin{bmatrix} 1 & 0 & 0 & \ldots & 0 \end{bmatrix}.$$

The system has been transformed into a string of integrators plus additional dynamics that is unobservable from the output.

By suitable choice of additional feedback $v = K\zeta$, one can insure that the poles of $F + GK$ are stable. The stability of the overall system then depends on the stability of the zero dynamics (Byrnes and Isidori 1984, 1988),

$$\dot{\xi} = \phi(0, \xi)$$

If this is stable, then the overall system will be stable. The zero dynamics is so-called because it is the dynamics that results from imposing the constraint $y(t) = 0$ on the system. For this to be satisfied, the initial value must satisfy $\zeta(0) = 0$ and the control must satisfy

$$u(t) = -\frac{f_r(0, \xi(t))}{g_r(0, \xi(t))}$$

Similar results hold in the multiple input, multiple output case, see Isidori (1995) for the details.

Approximate Feedback Linearization

Since so few controlled dynamics are exactly feedback linearizable, Krener (1984) introduced the concept of approximate feedback linearization. The goal is to find a smooth local change of coordinates and a smooth feedback

$$z = \phi(x), \qquad u = \alpha(x) + \beta(x)v$$

transforming the affinity controlled dynamics (3) to

$$\dot{z} = Fz + Gv + N(x, u)$$

where the nonlinearity $N(x, u)$ is small in some sense. In the design process, the nonlinearity is ignored, and the controller design is done on the linear model and then transformed back into a controller for the original system.

The power series approach of Poincaré was taken by Krener et al. (1987, 1988, 1991), Krener (1990), and Krener and Maag (1991). See also Kang (1994). It is applicable to dynamics which may not be affine in the control. The controlled nonlinear dynamics (2), the change of coordinates, and the feedback are expanded in a power series

$$\dot{x} = Fx + Gu + f^{[2]}(x, u) + O(x, u)^3$$

$$z = x - \phi^{[2]}(x)$$

$$v = u - \alpha^{[2]}(x, u)$$

The transformed system is

$$\dot{z} = Fz + Gv + f^{[2]}(x, u)$$

$$- \left[Fx + Gu, \phi^{[2]}(x) \right] + G\alpha^{[2]}(x, u)$$

$$+ O(x, u)^3$$

To eliminate the quadratic terms, one seeks a solution of the degree two homological equations for $\phi^{[2]}$, $\alpha^{[2]}$

$$\left[Fx + Gu, \phi^{[2]}(x) \right] - G\alpha^{[2]}(x, u) = f^{[2]}(x, u)$$

Unlike before, the degree two homological equations are not square. Almost always, the number of unknowns is less than the number of equations. Furthermore, the the mapping

$$\left(\phi^{[2]}(x), \alpha^{[2]}(x, u) \right) \mapsto \left[Fx + Gu, \phi^{[2]}(x) \right]$$

$$-G\alpha^{[2]}(x, u)$$

is less than full rank. Hence, only an approximate, e.g., a least squares solution, is possible. Krener has written a MATLAB toolbox (http://www.math.ucdavis.edu/ krener 1995) to compute term by term solutions to the homological equations. The routine **fh2f_h_.m** sequentially computes the least square solutions of the homological equations to arbitrary degree.

Observers with Linearizable Error Dynamics

The dual of linear state feedback is linear input–output injection. Linear input–output injection is the transformation carrying

$$\dot{x} = Fx + Gu$$

$$y = Hx$$

into

$$\dot{x} = Fx + Bu + Ly + Mu$$

$$y = Hx$$

Linear input–output injection and linear change of state coordinates

$$\dot{x} = Fx + Bu + Ly + Mu$$

$$y = Hx$$

$$z = Tx$$

$$\dot{z} = TFT^{-1}x + TLy + TMu$$

define a group action on the class of linear systems. Of course, output injection is not physically realizable on the original system, but it is realizable on the observer error dynamics.

Nonlinear input–output injection is not well defined independent of the coordinates; input–output injection in one coordinate system does not look like input–output injection in another coordinate system.

If a system

$$\dot{x} = f(x, u), \qquad y = h(x)$$

can be transformed by nonlinear changes of state and output coordinates

$$z = \phi(x), \qquad w = \gamma(y)$$

to a linear system with nonlinear input–output injection

$$\dot{z} = Fz + Gu + \alpha(y, u)$$

$$w = Hz$$

then the observer

$$\dot{\hat{z}} = (F + LH)\hat{z} + Gu + \alpha(y, u) - Lw$$

has linear error dynamics

$$\tilde{z} = z - \hat{z}$$

$$\dot{\tilde{z}} = (F + LH)\tilde{z}$$

If H, F is detectable, then $F + LH$ can be made Hurwitz, i.e., all its eigenvalues are in the open left half plane.

The case when $\gamma = $ identity, there are no inputs $m = 0$ and one output $p = 1$,

$$\dot{x} = f(x)$$

$$y = h(x)$$

was solved by Krener and Isidori (1983) and Bestle and Zeitz (1983) when the pair H, F defined by

$$F = \frac{\partial f}{\partial x}(0)$$

$$H = \frac{\partial h}{\partial x}(0)$$

is observable.

One seeks a change of coordinates $z = \phi(x)$ so that the system is linear up to output injection

$$\dot{z} = Fz + \alpha(y)$$

$$y = Hz$$

If they exist, the z coordinates satisfy the PDE's

$$L_{ad^{n-k}(f)g}(z_j) = \delta_{k,j}$$

where the vector field $g(x)$ is defined by

$$L_g L_f^{k-1} h = \begin{cases} 0 & 1 \le k < n \\ 1 & k = n \end{cases}$$

The solvability conditions for these PDE's are that for $1 \le k < l \le n - 1$

$$\left[ad^{k-1}(f)g, ad^{l-1}(f)g \right] = 0.$$

The general case with γ, m, p arbitrary was solved by Krener and Respondek (1985). The solution is a three-step process. First, one must set up and solve a linear PDE for $\gamma(y)$. The integrability conditions for this PDE involve the vanishing of a pseudo-curvature (Krener 1986). The next two steps are similar to the above.

One defines a vector field g^j, $1 \leq j \leq p$ for each output, these define a PDE for the change of coordinates, for which certain integrability conditions must be satisfied. The process is more complicated than feedback linearization and even less likely to be successful so approximate solutions must be sought which we will discuss later in this section. We refer the reader Krener and Respondek (1985) and related work Zeitz (1987) and Xia and Gao (1988a,b, 1989).

Very few systems can be linearized by change of state coordinates and input–output injection, so Krener et al. (1987, 1988, 1991), Krener (1990), and Krener and Maag (1991) sought approximate solutions by the power series approach. Again, the system, the changes of coordinates, and the output injection are expanded in a power series. See the above references for details.

Conclusion

We have surveyed the various ways a nonlinear system can be approximated by a linear system.

Abstract

We consider the simplest design problem for nonlinear systems: the problem of rendering asymptotically stable a given equilibrium by means of state feedback. For such a problem, we provide a necessary condition, known as Brockett condition, and a sufficient condition, which relies upon the definition of a class of functions, known as control Lyapunov functions. The theory is illustrated by means of a few examples. In addition, we discuss a nonlinear enhancement of the so-called separation principle for stabilization by means of partial state information.

Keywords

Brockett theorem; Control Lyapunov function; Output feedback; State feedback

Introduction

The problem of feedback stabilization, namely, the problem of designing a feedback control law locally, or globally, asymptotically stabilizing a given equilibrium point, is the simplest design

problem for nonlinear systems. If the state of the system is available for feedback, then the problem is referred to as the state feedback stabilization problem, whereas if only part of the state, for example, an output signal, is available for feedback, the problem is referred to as the partial state feedback (or output feedback) stabilization problem. We initially focus on the state feedback stabilization problem, which can be formulated as follows.

Consider a nonlinear system described by the equation

$$\dot{x} = F(x, u), \tag{1}$$

where $x(t) \in IR^n$ denotes the state of the system, $u(t) \in IR^m$ denotes the input of the system, and $F : IR^n \times IR^m \to IR^n$ is a smooth mapping.

Let $x_0 \in IR^n$ be an *achievable* equilibrium, i.e., x_0 is such that there exists a constant $u_0 \in IR^m$ such that $F(x_0, u_0) = 0$. The state feedback stabilization problem consists in finding, if possible, a state feedback control law, described by the equation

$$u = \alpha(x), \tag{2}$$

with $\alpha : IR^n \to IR^m$, such that the equilibrium x_0 is a locally asymptotically stable equilibrium for the closed-loop system

$$\dot{x} = F(x, \alpha(x)). \tag{3}$$

Alternatively, one could require that the equilibrium be globally asymptotically stable. Note that it is not always possible to *extend* local properties to global properties. For example, for the system described by the equations $\dot{x}_1 = x_2(1 - x_1^2)$, $\dot{x}_2 = u$, with $x_1(t) \in IR$, $x_2(t) \in IR$, and $u(t) \in IR$, it is not possible to design a feedback law which renders the zero equilibrium globally asymptotically stable.

If only partial information on the state is available, then one has to resort to a dynamic *output* feedback controller, namely, a controller described by equations of the form

$$\dot{\xi} = \beta(\xi, y), \qquad u = \alpha(\xi), \tag{4}$$

where $\xi(t) \in IR^\nu$ describes the state of the controller, $y(t) \in IR^p$ is given by $y = h(x)$, for some mapping $h : IR^n \to IR^p$, and describes the available information on the state x, and $\beta : IR^\nu \times IR^p \to IR^\nu$ and $\alpha : IR^\nu \to IR^m$ are smooth mappings. Within this scenario, the stabilization problem boils down to selecting the (nonnegative) integer ν (i.e., the order of the controller), a constant $\xi_0 \in IR^\nu$, and the mappings α and β such that the closed-loop system

$$\dot{x} = F(x, \alpha(\xi)), \qquad \dot{\xi} = \beta(\xi, h(x)), \tag{5}$$

has a locally (or globally) asymptotically stable equilibrium at (x_0, ξ_0). Alternatively, one may require that the equilibrium (x_0, ξ_0) of the closed-loop system (5) be locally asymptotically stable with a region of attraction that contains a given, user-specified, set.

The rest of the entry is organized as follows. We begin discussing two key results. The first is a necessary condition, due to R.W. Brockett, for continuous stabilizability. This provides an obstruction to the solvability of the problem and can be used to show that, for nonlinear systems, controllability does not imply stabilizability by continuous feedback. The second one is the extension of the Lyapunov direct method to systems with control. The main idea is the introduction of a control version of Lyapunov functions, the *control Lyapunov functions*, which can be used to design stabilizing control laws by means of a *universal formula*. We then describe two classes of systems for which it is possible to construct, with systematic procedures, smooth control laws yielding global asymptotic stability of a given equilibrium: systems in feedback and in feedforward form. There are several other constructive and systematic stabilization methods which have been developed in the last few decades. Worth mentioning are passivity-based methods and center manifold-based methods.

We conclude the entry describing a nonlinear version of the separation principle for the asymptotic stabilization, by output feedback, of a general class of nonlinear systems.

Preliminary Results

To highlight the difficulties and peculiarities of the nonlinear stabilization problem, we recall some basic facts from linear systems theory and exploit such facts to derive a sufficient condition and a necessary condition. In the case of linear systems, i.e., systems described by the equation $\dot{x} = Ax + Bu$, with $A \in IR^{n \times n}$ and $B \in IR^{n \times m}$, and linear state feedback, i.e., feedback described by the equation $u = Kx$, with $K \in IR^{m \times n}$, the stabilization problem boils down to the problem of placing, in the complex plane, the eigenvalues of the matrix $A + BK$ to the left of the imaginary axis. This problem is solvable if and only if the uncontrollable modes of the system are located, in the complex plane, to the left of the imaginary axis.

The linear theory may be used to provide a simple obstruction to feedback stabilizability and a simple sufficient condition. Let x_0 be an achievable equilibrium with $u_0 = 0$ and note that the linear approximation of the system (1) around x_0 is described by an equation of the form $\dot{x} = Ax + Bu$.

If for any $K \in IR^{m \times n}$ the condition

$$\sigma(A + BK) \cap C^+ \neq \emptyset \qquad (6)$$

holds, then the equilibrium of the nonlinear system cannot be stabilized by any continuously differentiable feedback such that $\alpha(x_0) = 0$. The notation $\sigma(A)$ denotes the spectrum of the matrix A, i.e., the eigenvalues of A. Note however that, if the condition $\alpha(x_0) = 0$ is dropped, the obstruction does not hold: the zero equilibrium of $\dot{x} = x + xu$ is not stabilizable by any continuous feedback such that $\alpha(0) = 0$, yet the *feedback* $u = -2$ is a (global) stabilizer.

On the contrary, if there exists a K such that

$$\sigma(A + BK) \subset C^-$$

then the feedback $\alpha(x) = Kx$ locally asymptotically stabilizes the equilibrium x_0 of the closed-loop system. This fact is often referred to as *the linearization approach*.

The above linear arguments are often inadequate to design feedback stabilizers: a theory for nonlinear feedback has to be developed. However, this theory is much more involved. In particular, it is important to observe that the solvability of the stabilization problem may depend upon the regularity properties of the feedback, i.e., of the mapping α. In fact, a given equilibrium of a nonlinear system may be rendered locally asymptotically stable by a continuous feedback, whereas there may be no continuously differentiable feedback achieving the same goal. If the feedback is required to be continuously differentiable, then the problem is often referred to as the *smooth* stabilization problem.

Example 1 To illustrate the role of the regularity properties of the feedback, consider the system described by the equations

$$\dot{x}_1 = x_1 - x_2^3, \qquad \dot{x}_2 = u,$$

with $x_1(t) \in IR$, $x_2(t) \in IR$, and $u(t) \in IR$, and the equilibrium $x_0 = (0,0)$. The equilibrium is globally asymptotically stabilized by the continuous feedback

$$\alpha(x) = -x_2 + x_1 + \frac{4}{3}x_1^{\frac{1}{3}} - x_2^3,$$

but it is not stabilizable by any continuously differentiable feedback. Note, in fact, that condition (6) holds.

Brockett Theorem

Brockett's necessary condition, which is far from being sufficient, provides a simple test to rule out the existence of a continuous stabilizer.

Theorem 1 *Consider the system (1) and assume $x_0 = 0$ is an achievable equilibrium with $u_0 = 0$.*

Assume there exists a continuous stabilizing feedback $u = \alpha(x)$. Then, for each $\epsilon > 0$ there exists $\delta > 0$ such that, for all y with $||y|| < \delta$, the equation $y = F(x, u)$ has at least one solution in the set $||x|| < \epsilon$, $||u|| < \epsilon$.

Theorem 1 can be reformulated as follows. The existence of a continuous stabilizer implies that the image of the mapping $F : IR^n \times IR^m \to IR^n$ covers a neighborhood of the origin. Note, in addition, that the obstruction expressed by Theorem 1 is of topological nature. Hence, it requires continuity of F and α, and time invariance: it does not hold if $u = \alpha(x, t)$, i.e., a time-varying feedback is designed.

In the linear case, Brockett condition reduces to the condition

$$\text{rank}[A - \lambda I, \ B] = n$$

for $\lambda = 0$. This is a necessary, but clearly not sufficient, condition for the stabilizability of $\dot{x} = Ax + Bu$.

Example 2 Consider the kinematic model of a mobile robot given by the equations

$$\begin{aligned} \dot{x} &= \cos \theta \, v, \\ \dot{y} &= \sin \theta \, v, \\ \dot{\theta} &= \omega, \end{aligned}$$

where $(x(t), y(t)) \in IR^2$ denotes the Cartesian position of the robot, $\theta(t) \in (-\pi, \pi]$ denotes the robot orientation (with respect to the x-axis), $v(t) \in IR$ is the forward velocity of the robot, and $\omega(t) \in IR$ is its angular velocity. Simple intuitive considerations suggest that the system is controllable, i.e., it is possible to select the forward and angular velocities to drive the robot from any initial position/orientation to any final position/orientation in any given positive time. Nevertheless, the zero equilibrium (and any other equilibrium of the system) is not continuously stabilizable. In fact, the equations

$$y_1 = \cos \theta \, v, \qquad y_2 = \sin \theta \, v, \qquad y_3 = \omega,$$

with $||(y_1, y_2, y_3)|| < \delta$ and $||(x, y, \theta)|| < \epsilon$, $||(v, \omega)|| < \epsilon$, are in general not solvable. For example, if $\epsilon < \pi/2$ and $y_1 = 0$, $y_2 \neq 0$, $y_3 = 0$, then the unique solution of the first and third equations is $v = 0$ and $\omega = 0$, implying $\sin \theta \, v = 0$; hence, the second equation does not have a solution.

Control Lyapunov Functions

The Lyapunov theory states that the equilibrium x_0 of the system

$$\dot{x} = f(x),$$

with $f : IR^n \to IR^n$, is locally asymptotically stable if there exists a continuously differentiable function $V : IR^n \to IR$, called Lyapunov function, and a neighborhood U of x_0 such that $V(x_0) = 0$, $V(x) > 0$, for all $x \in U$ and $x \neq x_0$, and $\frac{\partial V}{\partial x} f(x) < 0$, for all $x \in U$ and $x \neq x_0$.

To apply this idea to the stabilization problem, consider the system (1). If the equilibrium x_0 of $\dot{x} = F(x, u)$ is continuously stabilizable, then there must exist a continuously differentiable function V and a neighborhood U of x_0 such that

$$\inf_u \frac{\partial V}{\partial x} F(x, u) < 0,$$

for all $x \in U$ and $x \neq x_0$. This motivates the following definition.

Definition 1 A continuously differentiable function V such that

- $V(x_0) = 0$ and $V(x) > 0$, for all $x \in U$ and $x \neq x_0$,
- $\inf_u \frac{\partial V}{\partial x} F(x, u) < 0$, for all $x \in U$ and $x \neq x_0$,

is called a *control Lyapunov function*.

By Lyapunov theory, the existence of a continuous stabilizer implies the existence of a control Lyapunov function. On the other hand, the existence of a control Lyapunov function does not guarantee the existence of a stabilizer. However, in the case of systems affine in the control, i.e., systems described by the equation

$$\dot{x} = f(x) + g(x)u, \tag{7}$$

with $f : IR^n \to IR^n$ and $g : IR^n \to IR^{n \times m}$ smooth mappings, very general results can be proven. These have been proven by Z. Artstein, who gave a nonconstructive statement, and have been given a constructive form by E.D. Sontag.

In particular, for single-input nonlinear systems, the following statement holds.

Theorem 2 *Consider the system (7), with $m = 1$, and assume $f(0) = 0$.*

There exists an almost smooth feedback, i.e., the feedback $\alpha(x)$ is continuously differentiable for all $x \in IR^n$ and $x \neq 0$, and continuous at $x = 0$ which globally asymptotically stabilizes the equilibrium $x = 0$ if and only if there exists a positive definite, radially unbounded, i.e., $\lim_{\|x\| \to \infty} V(x) = \infty$ and smooth function $V(x)$ such that

1. $\dfrac{\partial V}{\partial x} g(x) = 0 \quad \Rightarrow \quad \dfrac{\partial V}{\partial x} f(x) < 0$, *for all $x \neq 0$;*
2. *For each $\epsilon > 0$ there is a $\delta > 0$ such that $\|x\| < \delta$ implies that there is a $|u| < \epsilon$ such that*

$$\frac{\partial V}{\partial x} f(x) + \frac{\partial V}{\partial x} g(x) u < 0.$$

Condition 2 is known as the *small control property*, and it is necessary to guarantee continuity of the feedback at $x = 0$. If Conditions 1 and 2 hold, then an almost smooth feedback is given by the so-called Sontag's universal formula:

$$\alpha(x) = \begin{cases} 0, & \text{if } \dfrac{\partial V}{\partial x} g(x) = 0, \\[4mm] -\dfrac{\frac{\partial V}{\partial x} f(x) + \sqrt{\left(\frac{\partial V}{\partial x} f(x)\right)^2 + \left(\frac{\partial V}{\partial x} g(x)\right)^4}}{\frac{\partial V}{\partial x} g(x)}, & \text{elsewhere.} \end{cases}$$

Constructive Stabilization

We now introduce two classes of nonlinear systems for which systematic design methods to solve the state feedback stabilization problem are available.

Feedback Systems

Consider a nonlinear system described by equations of the form

$$\dot{x}_1 = f_1(x_1, x_2), \qquad \dot{x}_2 = u, \qquad (8)$$

with $x_1(t) \in IR^n$, $x_2(t) \in IR$, $u(t) \in IR^n$ and $f_1(0, 0) = 0$. This system belongs to the so-called class of feedback systems for which a sort of reduction principle holds: the zero equilibrium of the system is smoothly stabilizable if the same holds for the *reduced* system $\dot{x}_1 = f(x_1, v)$, which is obtained from the first of Eq. (8) replacing the state variable x_2 with a *virtual control* input v. To show this property, suppose there exist a continuously differentiable function $\alpha_1 : IR^n \to IR$ and

a continuously differentiable and radially unbounded function $V_1 : IR^n \to IR$ such that $V_1(0) = 0$, $V_1(x_1) > 0$, for all $x_1 \neq 0$, and

$$\frac{\partial V_1}{\partial x_1} f(x_1, \alpha_1(x_1)) < 0,$$

for all $x_1 \neq 0$, i.e., the zero equilibrium of the system $\dot{x}_1 = f(x_1, v)$ is globally asymptotically stabilizable.

Consider now the function

$$V(x_1, x_2) = V_1(x_1) + \frac{1}{2}(x_2 - \alpha_1(x_1))^2,$$

which is radially unbounded and such that $V(0, 0) = 0$ and $V(x_1, x_2) > 0$ for all nonzero (x_1, x_2), and note that

$$\begin{aligned} \dot{V} &= \frac{\partial V_1}{\partial x_1} f(x_1, x_2) + (x_2 - \alpha_1(x_1)) \\ &\quad \times (u + \Delta_1(x_1, x_2)) \\ &= \frac{\partial V_1}{\partial x_1} f(x_1, \alpha_1(x_1)) + (x_2 - \alpha_1(x_1)) \\ &\quad \times (u + \Delta_2(x_1, x_2)), \end{aligned}$$

for some continuously differentiable mappings Δ_1 and Δ_2. As a result, the feedback

$$\alpha(x_1, x_2) = -\Delta_2(x_1, x_2) - k(x_2 - \alpha_1(x_1)),$$

with $k > 0$, yields $\dot{V} < 0$ for all nonzero (x_1, x_2); hence, the feedback is a continuously differentiable stabilizer for the zero equilibrium of the system (8). Note, finally, that the function V is a control Lyapunov for the system (8); hence, Sontag's formula can be also used to construct a stabilizer.

The result discussed above is at the basis of the so-called backstepping technique for recursive stabilization of systems described, for example, by equations of the form

$$\begin{aligned}
\dot{x}_1 &= x_2 + \varphi_1(x_1), \\
\dot{x}_2 &= x_3 + \varphi_2(x_1, x_2), \\
\dot{x}_3 &= x_4 + \varphi_3(x_1, x_2, x_3), \\
&\vdots \\
\dot{x}_n &= u + \varphi_n(x_1, \ldots, x_n),
\end{aligned}$$

with $x_i(t) \in I\!R$ for all $i \in [1, n]$, and φ_i smooth mappings such that $\varphi_i(0) = 0$, for all $i \in [1, n]$.

Feedforward Systems
Consider a nonlinear system described by equations of the form

$$\dot{x}_1 = f_1(x_2), \qquad \dot{x}_2 = f_2(x_2) + g_2(x_2)u, \quad (9)$$

with $x_1(t) \in I\!R$, $x_2(t) \in I\!R^n$, $u(t) \in I\!R$, $f_1(0) = 0$ and $f_2(0) = 0$. This system belongs to the so-called class of feedforward systems for which, similarly to feedback systems, a sort of reduction principle holds: the zero equilibrium of the system is smoothly stabilizable if the zero equilibrium of the *reduced* system $\dot{x}_2 = f(x_2)$ is globally asymptotically stable and some additional structural assumption holds. To show this property, suppose there exists a continuously differentiable and radially unbounded function $V_2 : I\!R^n \to I\!R$ such that $V_2(0) = 0$, $V_2(x_2) > 0$, for all $x_2 \neq 0$, and

$$\frac{\partial V_2}{\partial x_2} f_2(x_2) < 0,$$

for all $x_2 \neq 0$. Suppose, in addition, that there exists a continuously differentiable mapping $M(x_2)$ such that

$$f_1(x_2) - \frac{\partial M}{\partial x_2} f_2(x_2) = 0,$$

$M(0) = 0$ and $\left. \dfrac{\partial M}{\partial x_2} \right|_{x_2=0} \neq 0$. Existence of such a mapping is guaranteed, for example, by asymptotic stability of the linearization of the system $\dot{x}_2 = f_2(x_2)$ around the origin and controllability of the linearization of the system (9) around the origin.

Consider now the function

$$V(x_1, x_2) = \frac{1}{2}(x_1 - M(x_2))^2 + V_2(x_2),$$

which is radially unbounded and such that $V(0, 0) = 0$ and $V(x_1, x_2) > 0$ for all nonzero (x_1, x_2), and note that

$$\begin{aligned}
\dot{V} &= -(x_1 - M(x_2))\frac{\partial M}{\partial x_2} g_2(x_2)u + \frac{\partial V_2}{\partial x_2} f_2(x_2) \\
&\quad + \frac{\partial V_2}{\partial x_2} g_2(x_2)u \\
&= \frac{\partial V_2}{\partial x_2} f_2(x_2) + \left(\frac{\partial V_2}{\partial x_2} - (x_1 - M(x_2))\frac{\partial M}{\partial x_2} \right) \\
&\quad \times g_2(x_2)u.
\end{aligned}$$

As a result, the feedback

$$\begin{aligned}
\alpha(x_1, x_2) = -k &\left(\frac{\partial V_2}{\partial x_2} - (x_1 - M(x_2))\frac{\partial M}{\partial x_2} \right) \\
&\times g_2(x_2),
\end{aligned}$$

with $k > 0$, yields $\dot{V} < 0$ for all nonzero (x_1, x_2); hence, the feedback is a continuously differentiable stabilizer for the zero equilibrium of the system (9). Note, finally, that the function V is a control Lyapunov for the system (9); hence, Sontag's formula can be also used to construct a stabilizer.

The result discussed above is at the basis of the so-called forwarding technique for recursive stabilization of systems described, for example, by equations of the form

$$\begin{aligned}
\dot{x}_1 &= \varphi_1(x_2, \ldots, x_n), \\
\dot{x}_2 &= \varphi_2(x_3, \ldots, x_n), \\
&\vdots \\
\dot{x}_{n-1} &= \varphi_{n-1}(x_n), \\
\dot{x}_n &= u,
\end{aligned}$$

with $x_i(t) \in I\!R$ for all $i \in [1, n]$, and φ_i smooth mappings such that $\varphi_i(0) = 0$, for all $i \in [1, n]$.

Stabilization via Output Feedback

In the previous sections, we have studied the stabilization problem for nonlinear systems under the assumption that the whole state is available for feedback. This requires the online measurement of the state vector x, which may pose a severe constrain in applications. This observation motivates the study of the much more challenging, but more realistic, problem of stabilization with partial state information. This problem requires the introduction of a notion of observability. Note that for nonlinear systems, it is possible to define several, nonequivalent, observability notions. Similarly to section "Control Lyapunov Functions", we focus on the class of systems affine in the control, i.e., systems described by equations of the form

$$\begin{aligned}
\dot{x} &= f(x) + g(x)u, \\
y &= h(x),
\end{aligned} \tag{10}$$

with $f : I\!R^n \to I\!R^n$, $g : I\!R^n \to I\!R^{n \times m}$ and $h : I\!R^n \to I\!R^p$ smooth mappings. This is precisely the class of systems in Eq. (7) with the addition of the *output map h*, i.e., a map which describes the information that is available for feedback. In addition, we assume, to simplify the notation, that $m = 1$ and $p = 1$: the system is single input, single output. Finally assume, without loss of generality, that the equilibrium to be stabilized is $x_0 = 0$, that any stabilizing state feedback control law $u = \alpha(x)$ is such that $\alpha(0) = 0$, and that $h(0) = 0$.

To define the observability notion of interest, consider the sequence of mappings

$$\phi_0(x) = h(x),$$

$$\phi_1(x, v_0) = \frac{\partial \phi_0}{\partial x} [f(x) + g(x)v_0],$$

$$\phi_2(x, v_0, v_1) = \frac{\partial \phi_1}{\partial x}[f(x) + g(x)v_0] + \frac{\partial \phi_1}{\partial v_0} v_1,$$

$$\cdots$$

$$\begin{aligned}
\phi_k(x, v_0, v_1, \cdots, v_{k-1}) &= \frac{\partial \phi_{k-1}}{\partial x} \\
&\times [f(x) + g(x)v_0] \\
&+ \sum_{i=0}^{k-2} \frac{\partial \phi_{k-1}}{\partial v_i} v_{i+1},
\end{aligned} \tag{11}$$

with $k \le n$. Note that if $u(t)$ is of class C^{k-1}, then

$$y^{(k)}(t) = \phi_k(x(t), u(t), \cdots, u^{(k-1)}(t)),$$

where the notation $y^{(k)}(t)$, with k positive integer, is used to denote the k-th order derivative of the function $y(t)$, provided it exists. The mappings ϕ_0 to ϕ_{n-1} can be collected into a unique mapping $\Phi : I\!R^n \times I\!R^{n-1} \to I\!R^n$ defined as

$$\Phi(x, v_0, v_1, \cdots, v_{n-2})$$
$$= \begin{bmatrix} \phi_0(x) \\ \phi_1(x, v_0) \\ \vdots \\ \phi_{n-1}(x, v_0, v_1, \cdots, v_{n-2}) \end{bmatrix}.$$

The mapping Φ is, by construction, such that

$$\Phi(x(t), u(t), \dot{u}(t), \cdots, u^{(n-2)}(t))$$
$$= \begin{bmatrix} y(t) \ \dot{y}(t) \cdots y^{(n-1)}(t) \end{bmatrix}',$$

for any t in which the indicated signals exist. As a consequence, if the mapping Φ is such that, as some point $(\bar{x}, \bar{v})$, where $\bar{v} = \begin{bmatrix} \bar{v}_0 \ \bar{v}_1 \cdots \bar{v}_{n-2} \end{bmatrix}'$,

$$\text{rank}\frac{\partial \Phi}{\partial x}(\bar{x}, \bar{v}) = n, \qquad (12)$$

then, by the Implicit Function Theorem, there exists locally around $(\bar{x}, \bar{v})$ a smooth mapping $\Psi : IR^n \times IR^{n-1} \to IR^n$ such that

$$\omega = \Phi(\Psi(\omega, v), v),$$

i.e., the mapping Ψ is the *inverse* of Φ, parameterized by v. We conclude the discussion noting that if, at a certain time $\bar{t}$, $\bar{x} = x(\bar{t})$ and $\bar{v} = \left[u(\bar{t}) \; \dot{u}(\bar{t}) \cdots u^{(n-2)}(\bar{t}) \right]'$ are such that the rank condition (12) holds, then the mapping Ψ can be used to reconstruct the state of the system from measurements of the input, and its derivatives, and the output and its derivatives, for all t in a neighborhood of $\bar{t}$: $x(t) = \Psi(\omega(t), v(t))$, for all t in a neighborhood of $\bar{t}$, where

$$v(t) = \left[u(t) \; \dot{u}(t) \cdots u^{(n-2)}(t) \right]',$$
$$\omega(t) = \left[y(t) \; \dot{y}(t) \cdots y^{(n-1)}(t) \right]'. \qquad (13)$$

This property is a local property: to derive a property which allows a global reconstruction of the state, we need to impose additional conditions.

Definition 2 Consider the system (10) with $m = p = 1$. The system is said to be *uniformly observable* if:

(i) The mapping $H : IR^n \to IR^n$ defined as

$$H(x) = \begin{bmatrix} h(x) \\ L_f h(x) \\ \vdots \\ L_f^{n-1} h(x) \end{bmatrix}$$

is a global diffeomorphism. The functions $L_f^i h$, with i nonnegative integer, are defined as $L_f h(x) = L_f^1 h(x) = \frac{\partial h}{\partial x} f(x)$ and, recursively, as $L_f^{i+1} h(x) = L_f(L_f^i h(x))$.

(ii) The rank condition (12) holds for all $(x, v) \in IR^n \times IR^{n-1}$.

The notion of uniform observability allows to *perform* a global reconstruction of the state, i.e., it makes sure that the identities

$$\omega = \Phi(\Psi(\omega, v), v) \qquad x = \Psi(\Phi(x, v), v)$$

hold for all x, v and ω. In principle, this property may be used in an output feedback control architecture obtained implementing a stabilizing state feedback $u = \alpha(x)$ as $u = \alpha(\Psi(\omega, v))$, with v and ω as given in (13). This implementation is however not possible, since it gives an implicit definition of u and requires the exact differentiation of the input and output signals.

To circumvent these difficulties, one needs to follow a somewhat longer path, as described hereafter. In addition, the global asymptotic stability requirement should be replaced by a less ambitious, yet practically meaningful, requirement: semi-global asymptotic stability. This requirement can be formalized as follows.

Definition 3 The equilibrium x_0 of the system (1), or (7), is said to be semi-globally asymptotically stabilizable if, for each compact set $\mathcal{K} \subset IR^n$ such that $x_0 \in \text{int}(\mathcal{K})$, i.e. the set of all interior points of $\mathcal{K}$, there exists a feedback control law, possibly depending on $\mathcal{K}$, such that the equilibrium x_0 is a locally asymptotically stable equilibrium of the closed-loop system and for any $x(0) \in \mathcal{K}$ one has $\lim_{t \to \infty} x(t) = x_0$.

To bypass the need for the derivatives of the input signal, consider the extended system

$$\dot{x} = f(x) + g(x)v_0, \qquad \dot{v}_0 = v_1,$$
$$\dot{v}_1 = v_2, \quad \cdots \quad \dot{v}_{n-1} = \tilde{u}. \qquad (14)$$

Note that, as described in section "Feedback Systems", if the equilibrium $x_0 = 0$ of the system $\dot{x} = f(x) + g(x)u$ is globally asymptotically stabilizable by a (smooth) feedback $u = \alpha(x)$, then there exists a smooth state feedback $\tilde{u} = \tilde{\alpha}(x, v_0, v_1, \cdots, v_{n-1})$ which globally asymptotically stabilizes the zero equilibrium of the system (14). In the feedback $\tilde{\alpha}$, one can replace x with $\psi(\omega, v)$, thus yielding a feedback of the measurable part of the state of the system (14) and of the output y and its derivatives. Note that if $\omega(t) = \left[y(t) \; \dot{y}(t) \cdots y^{(n-1)}(t) \right]'$, then the feedback $\tilde{u} = \tilde{\alpha}(\psi(\omega, v), v_0, v_1, \cdots, v_{n-1})$ globally asymptotically stabilizes the zero equilibrium of the system (14).

To avoid the computation of the derivatives of y, we exploit the uniform observability property, which implies that the auxiliary system

$$\begin{aligned} \dot{\eta}_0 &= \eta_1, \\ \dot{\eta}_1 &= \eta_2, \\ &\vdots \\ \dot{\eta}_{n-1} &= \phi_n(\psi(\eta, v), v_0, v_1, \cdots, v_{n-1}), \end{aligned} \quad (15)$$

with $\eta = \begin{bmatrix} \eta_0, \eta_1, \cdots, \eta_{n-1} \end{bmatrix}'$, has the property of reproducing $y(t)$ and its derivatives up to $y^{(n-1)}(t)$ if properly initialized. This initialization is not feasible, since it requires the knowledge of the derivative of the output at $t = 0$. Nevertheless, the auxiliary system (15) can be modified to provide an *estimate* of y and its derivatives. The modification is obtained adding a linear correction term yielding the system

$$\begin{aligned} \dot{\eta}_0 &= \eta_1 && + L\, c_{n-1}(y - \eta_0), \\ \dot{\eta}_1 &= \eta_2 && + L^2\, c_{n-2}(y - \eta_0), \\ &\vdots \\ \dot{\eta}_{n-1} &= \phi_n(\psi(\eta, v), v_0, v_1, \cdots, v_{n-1}) + L^n\, c_0(y - \eta_0), \end{aligned} \quad (16)$$

with $L > 0$ and the coefficients $c_0, \cdots, c_{n-1}$ such that all roots of the polynomial $\lambda^n + c_{n-1}\lambda^{n-1} + c_1\lambda + c_0$ are in C^-. The system (16) has the ability to provide asymptotic estimates of y and its derivatives up to $y^{(n-1)}$ provided these are bounded and the gain L is selected sufficiently large, i.e., the system (16) is a *semi-global* observer of y and its derivatives up to $y^{(n-1)}$.

The closed-loop system obtained using the feedback law $\tilde{u} = \tilde{\alpha}(\psi(\eta, v), v_0, v_1, \cdots, v_{n-1})$ has a locally asymptotically stable equilibrium at the origin. To achieve semi-global stability, one has to select L sufficient large and replace ψ with

$$\tilde{\psi}(\eta, v) = \begin{cases} \psi(\eta, v), & \text{if } \|\psi(\eta, v)\| < M, \\ M\, \dfrac{\psi(\eta, v)}{\|\psi(\eta, v)\|}, & \text{if } \|\psi(\eta, v)\| \geq M, \end{cases}$$

with $M > 0$ to be selected, as detailed in the following statement.

Theorem 3 *Consider the system (10) with $m = p = 1$. Let $x_0 = 0$ be an achievable equilibrium. Assume $h(0) = 0$. Suppose the system is uniformly observable and there exists a smooth state feedback control law $u = \alpha(x)$ which globally asymptotically stabilizes the zero equilibrium and it is such that $\alpha(0) = 0$.*

Then for each $R > 0$, there exist $\tilde{R} > 0$ and $M^\star > 0$, and for each $M > M^\star$, there exists $L^\star$

such that for each $M > M^\star$ and $L > L^\star$, the dynamic output feedback control law

$$\begin{aligned} \dot{v}_0 &= v_1, \\ \dot{v}_1 &= v_2, \\ &\vdots \\ \dot{v}_{n-1} &= \tilde{\alpha}(\tilde{\psi}(\eta, v), v_0, v_1, \cdots, v_{n-1}) \\ \dot{\eta}_0 &= \eta_1 + L\, c_{n-1}(y - \eta_0), \\ \dot{\eta}_1 &= \eta_2 + L^2\, c_{n-2}(y - \eta_0), \\ &\vdots \\ \dot{\eta}_{n-1} &= \phi_n(\psi(\eta, v), v_0, v_1, \cdots, v_{n-1}) \\ &\quad + L^n\, c_0(y - \eta_0), \\ u &= v_0, \end{aligned}$$

yields a closed-loop system with the following properties:
- *The zero equilibrium of the system is locally asymptotically stable.*
- *For any $x(0)$, $v(0)$ and $\eta(0)$ such that $\|x(0)\| < R$ and $\|(v(0), \eta(0))\| < \tilde{R}$, the trajectories of the closed-loop system are such that*

$$\lim_{t \to \infty} x(t) = 0, \qquad \lim_{t \to \infty} v(t) = 0,$$

$$\lim_{t \to \infty} \eta(t) = 0.$$

The foregoing result can be informally formulated as follows: global state feedback stabilizability and uniform observability imply semi-global stabilizability by output feedback. This can be regarded as a nonlinear enhancement of the so-called separation principle for the stabilization, by output feedback, of linear systems. Note, finally, that a global version of the separation principle can be derived under one additional assumption: the existence of an estimator of the norm of the state x.

Summary and Future Directions

A necessary condition and a sufficient condition for stabilizability of an equilibrium of a nonlinear system have been given, together with two systematic design methods. The necessary condition allows to rule out, using a simple algebraic test, existence of continuous stabilizers, whereas the sufficient condition provides a link with classical Lyapunov theory. In addition, the problem of semi-global stability by dynamic output feedback has been discussed in detail. Several issues have not been discussed, including the use of discontinuous, hybrid and time-varying feedbacks; stabilization by static output feedback and dynamic state feedback; robust stabilization. Note finally that similar considerations can be carried out for nonlinear discrete-time systems.

Abstract

Mathematical finance is an important part of applied mathematics since the 1980s. At the beginning, the main goal was to price derivative products and to provide hedging strategies. Nowadays, the goal is to provide models for prices and interest rates, such that better calibration of parameters can be done. In these pages, we present some basic models. Details can be found in Musiela and Rutkowski (2005).

Keywords

Models for Prices of Stocks

The first model of prices was elaborated by Louis Bachelier, in his thesis (1900). The idea was that the dynamic of prices has a trend, perturbed by a noise. For this noise, Bachelier set the fundamental properties of the Brownian motion. Bachelier's prices were of the form

$$S_t^B = S_0^B + \nu t + \sigma W_t$$

where W is a Brownian motion.

This model, where prices can take negative values, was changed by taking the exponential as in the celebrated Black-Scholes-Merton model (BSM) where

$$S_t = e^{S_t^B} = S_0 \exp(\nu t + \sigma W_t).$$

Only two constant parameters were needed; the coefficient σ is called the volatility. From Itô's formula, the dynamics of the BSM's price are

$$dS_t = S_t(\mu dt + \sigma dW_t)$$

where $\mu = \nu + \frac{1}{2}\sigma^2$. The interest rate is assumed to be a constant r.

The price of a derivative product of payoff $H \in \mathcal{F}_T = \sigma(S_s, s \leq T)$ is obtained using a hedging procedure. One proves that there exists a (self-financing) portfolio with value V, investing in the savings account and in the stock S, with terminal value H, i.e., $V_T = H$. The price of H at time t is V_t. Using that methodology, the price of a European call with strike K (i.e., for $H = (S_T - K)^+$) is

$$V_t = \mathcal{BS}(\sigma, K)_t := S_t \mathcal{N}(d_1) - Ke^{-r(T-t)}\mathcal{N}(d_2)$$

where $\mathcal{N}$ is the cumulative distribution function of a standard Gaussian law and

$$d_1 = \frac{1}{\sigma\sqrt{T-t}}\left(\ln\left(\frac{S_t}{Ke^{-r(T-t)}}\right)\right)$$
$$+ \frac{1}{2}\sigma\sqrt{T-t}, \ d_2 = d_1 - \sigma\sqrt{T-t}$$

Note that the coefficient μ plays no role in this pricing methodology. This formula opened the door to the notion of risk neutral probability measure: the price of the option (or of any derivative product) is the expectation under the unique probability measure $\mathbb{Q}$, equivalent to $\mathbb{P}$ such that the discounted price $S_t e^{-rt}, t \geq 0$ is a $\mathbb{Q}$ martingale.

During one decade, the financial market was quite smooth and this simple model was efficient to price derivative products and to calibrate the coefficients from the data. After the Black Monday of October 1987, the model was recognized to suffer some weakness and the door was fully

open to more sophisticated models, with more parameters. In particular, the smile effect was seen on the data: the BSM formula being true, the price of the option would be a deterministic function of the fixed parameter σ and of K (the other parameter as maturity, underlying price, interest rate being fixed), and one would obtain, using $\psi(\cdot, K)$, the inverse of $\mathcal{BS}(\cdot, K)$, the constant $\sigma = \psi(C^o(K), K)$, where $C^o(K)$ is the observed prices associated with the strike K. This is not the case, the curve $K \rightarrow \psi(C^o(K), K)$ having a smile shape (or a smirk shape). The BSM model is still used as a benchmark in the concept of implied volatility: for a given observed option price $C^o(K, T)$ (with strike K and maturity T), one can find the value of σ^* such that $\mathcal{BS}(\sigma^*, K, T) = C^o(K, T)$. The surface $\sigma^*(K, T)$ is called the implied volatility surface and plays an important role in calibration issues.

Due to the need of more accurate formula, many models were presented, the only (mathematical) restriction being that prices have to be semi-martingales (to avoid arbitrage opportunities).

A first class is the stochastic volatility models. Assuming that the diffusion coefficient (called the local volatility) is a deterministic function of time and underlying, i.e.,

$$dS_t = S_t(\mu dt + \sigma(t, S_t) dW_t)$$

Dupire proved, using Kolmogorov backward equation that the function σ is determined by the observed prices of call options by

$$\frac{1}{2}K^2\sigma^2(T, K) = \frac{\partial_T C^o(K, T) + rK\partial_K C^o(K, T)}{\partial^2_{KK} C^o(K, T)}$$

where ∂_T (resp. ∂_K) is the partial derivative operator with respect to the maturity (resp., the strike). However, this important model (which allows hedging for derivative products) does not allow a full calibration of the volatility surface.

A second class consists of assuming that the volatility is a stochastic process. The first example is the Heston model which assumes that

$$dS_t = S_t(\mu dt + \sqrt{v_t} dW_t)$$

$$dv_t = -\lambda(v_t - \bar{v})dt + \eta\sqrt{v_t} dB_t$$

where B and W are two Brownian motions with correlation factor ρ. This model is generalized by Gourieroux and Sufana (2003) as Wishart model where the risky asset S is a d dimensional process, with matrix of quadratic variation Σ satisfy

$$dS_t = \text{Diag}(S_t)(\mu dt + \sqrt{\Sigma_t} dW_t)$$
$$d\Sigma_t = (\Lambda\Lambda^T + M\Sigma_t + \Sigma_t M^T)dt$$
$$+ \sqrt{\Sigma_t}\, dB_t\, Q + Q^T\, (dB_t)^T\, \sqrt{\Sigma_t}$$

where W is a d dimensional Brownian motion and B a $(d \times d)$ matrix Brownian, Λ, M, Q are $(d \times d)$ matrices, M is semidefinite negative, and $\Lambda\Lambda^T = \beta QQ^T$ with $\beta \geq d - 1$ to ensure strict positivity. The efficiency of these models was checked using calibration methodology; however, the main idea of hedging for pricing issues is forgotten: there is, in general, no hedging strategy, even for common derivative products, and the validation of the model (the form of the volatility, since the drift term plays no role in pricing) is done by calibration. The risk neutral probability is no more unique.

Interest Rate Models

In the beginning of the 1970s, a specific attention was paid for the interest rate modeling, a constant interest rate being far from the real world.

A first class consists of a dynamic for the instantaneous interest rate r.

Vasisek suggested an Ornstein Uhlenbeck diffusion, i.e., $dr_t = a(b - r_t)dt + \sigma dW_t$, the solution being a Gaussian process of the form

$$r_t = (r_0 - b)e^{-at} + b + \sigma \int_0^t e^{-a(t-u)} dW_u.$$

This model is fully tractable, one of its weakness is that the interest rate can take negative values.

Cox, Ingersoll, and Rubinstein (CIR) studied the square root process

$$dr_t = a(b - r_t)dt + \sigma\sqrt{r_t}dB_t,$$

where $ab > 0$ (so that r is nonnegative). No closed form for r is known; however, closed form for the price of the associated zero coupons is known (see below in Affine Processes).

A second class is the celebrated Heath-Jarrow-Morton model (HJM): the starting point being to model the price of a zero coupon with maturity T (i.e., an asset which pays one monetary unit at time T, these prices being observable) in terms of the instantaneous forward rate $f(t, T)$, as

$$B(t, T) = \exp\left(-\int_t^T f(t, u)du\right).$$

Assuming that

$$df(t, T) = \alpha(t, T)dt + \sigma(t, T)dW_t$$

one finds

$$dB(t, T) = B(t, T)(a(t, T)dt + b(t, T)dW_t)$$

where the relationship between a, b and α, β is known. The instantaneous interest rate is $r_t = f(t, t)$. This model is quite efficient; however, no conditions are known in order that the interest rate is positive.

Models with Jumps

Lévy Processes

Following the idea to produce tractable models to fit the data, many models are now based on Lévy's processes. These models are used for modeling prices as $S_t = e^{X_t}$ where X is a Lévy process. They present a nice feature: even if closed forms for pricing are not known, numerical methods are efficient. One of the most popular is the Carr-Geman-Madan-Yor (CGMY) model which is a Lévy process without Gaussian component and with Lévy density

$$\frac{C}{x^{Y+1}}e^{-Mx}\mathbb{1}_{\{x>0\}} + \frac{C}{|x|^{Y+1}}e^{Gx}\mathbb{1}_{\{x<0\}}$$

with $C > 0$, $M \geq 0$, $G \geq 0$, and $Y < 2$.

These models are often presented as a special case of a change of time: roughly speaking, any semi-martingale is a time-changed Brownian motion, and many examples are constructed as $S_t = B_{A_t}$, where B is a Brownian motion and A an increasing process (the change of time), chosen independent of B (for simplicity) and A a Lévy process (for computational issues).

Affine Processes

Affine models were introduced by Duffie et al. (2003) and are now a standard tool for modeling stock prices, or interest rates. An affine process enjoys the property that, for any affine function g,

$$\mathbb{E}(\exp(uX_T + \int_t^T g(X_s)ds)|\mathcal{F}_t)$$
$$= \exp(\alpha(t, T)X_t + \beta(t, T))$$

where α and β are deterministic solutions of PDEs.

A class of affine processes X ($\mathbb{R}^n$-valued) is the one where

$$dX_t = b(X_t)dt + \sigma(X_t)dW_t + dZ_t$$

where the drift vector b is an affine function of x, the covariance matrix $\sigma(x)\sigma^T(x)$ is an affine function of x, W is an n-dimensional Brownian motion, and Z is a pure jump process whose jumps have a given law ν on $\mathbb{R}^n$ and arrive with intensity $f(X_t)$ where f is an affine function. An example is the CIR model (without jumps), where one can find the price of a zero coupon as

$$\mathbb{E}(\exp -\int_t^T r_s ds|\mathcal{F}_t)$$
$$= \Phi(T - t)\exp[-r_t\Psi(T - t)]$$

where

$$\Psi(s) = \frac{2(e^{\gamma s} - 1)}{(\gamma + a)(e^{\gamma s} - 1) + 2\gamma},$$

$$\Phi(s) = \left(\frac{2\gamma e^{(\gamma+a)\frac{s}{2}}}{(\gamma + a)(e^{\gamma s} - 1) + 2\gamma}\right)^{\frac{2ab}{\sigma^2}},$$

$$\gamma^2 = a^2 + 2\sigma^2.$$

Models for Defaults

At the end of 1990s, new kinds of financial products appear on the market: defaultable options, defaultable zero coupons, and credit derivatives, as the CDOs. Then, particular attention was paid to the modeling of default times; see Bielecki and Rutkowski ([2001](#)). The most popular model for a single default is the reduced form approach, which is based on the knowledge of the intensity rate process. Given a nonnegative process λ, adapted with respect to a reference filtration $\mathbb{F}$, a random time τ is defined so that

$$\mathbb{P}(\tau > t | \mathcal{F}_\infty) = \exp(-\int_0^t \lambda_s ds)$$

This implies that $\mathbb{1}_{\tau \leq t} - \int_0^{t \wedge \tau} \lambda_u du$ is a martingale (in the smallest filtration $\mathbb{G}$ which contains $\mathbb{F}$ and makes τ a random time). This intensity rate λ plays the role of the interest spread due to the equality, for any $Y \in \mathcal{F}_T$ and $\mathbb{F}$ adapted interest rate r

$$\mathbb{E}(Y \mathbb{1}_{T < \tau} \exp(-\int_t^T r_s ds) | \mathcal{G}_t) \mathbb{1}_{t < \tau}$$
$$= \mathbb{1}_{t < \tau} \mathbb{E}(Y \exp(-\int_t^T (r_s + \lambda_s) ds) | \mathcal{F}_t)$$

The real challenge is to model multi-defaults. Defaults are assumed to occur at times τ_i, and one has to describe the (conditional) joint law of the vector $\tau = (\tau_1, \tau_2, \ldots, \tau_n)$, the number n of defaults being quite large (100). A first step is to study the law of the defaults, i.e.,

$$\mathbb{P}(\tau_1 > t_1, \ldots, \tau_n > t_n)$$

which is performed using the classical copula approach, based on the knowledge of the marginal laws of the τ_i, i.e., on the knowledge of $\mathbb{P}(\tau_i \leq s) =: F_i(s)$ where the cumulative distribution functions F_i are assumed invertible. The simplest and most popular copula being the Gaussian one

$$\mathbb{P}(F_i^{-1}(\tau_i) \leq u_i, \ i = 1, \ldots, n)$$
$$= \mathcal{N}_\Sigma^n \left(\mathcal{N}^{-1}(u_1), \ldots, \mathcal{N}^{-1}(u_n) \right),$$

where $\mathcal{N}_\Sigma^n$ is the c.d.f. for the n-variate central normal distribution with the linear correlation matrix Σ and $\mathcal{N}^{-1}$ is the inverse of the c.d.f. for the univariate standard normal distribution. However, a dynamical model was needed, mainly to study the contagion effect, i.e., how the occurrence of a default affect the probability of occurrence of the next defaults.

A first class of models is based on the intensity: starting from a given family of intensities $(\lambda_t^i, i = 1, \ldots, n)$ which satisfies

$$d\lambda_t^i = f(t, \lambda_t^i) dt + g(t, \lambda_t^i) dW_t + dL_t^{(-i)}$$

where $L_t^{(-i)} = \sum_{k \neq i} \beta_k \mathbb{1}_{\tau_k \leq t}$, one constructs random times having the given intensities.

Another class of models, which allows for common jumps, is based on Markov Chains with absorbing state, the default time of the i-th entity being the time where the i-th component of the Markov Chain enters in the absorbing state. These models are efficient due to the introduction of common factors.

Many studies are done to find a form of a dynamic copula, i.e., a family of processes $G_t(\theta), t \geq 0$ such that

$$G_t(\theta) = \mathbb{P}(\tau_1 > \theta_1, \ldots, \tau_n > \theta_n | \mathcal{F}_t)$$

Some examples where, for any fixed t, the quantity $G_t(\cdot)$ is a (stochastic) Gaussian law are known; however, there are few concrete examples for other cases.

Flexible Robots

Alessandro De Luca
Sapienza Università di Roma, Roma, Italy

Abstract

Mechanical flexibility in robot manipulators is due to compliance at the joints and/or distributed deflection of the links. Dynamic models of the two classes of robots with flexible joints or flexible links are presented, together with control laws addressing the motion tasks of regulation to constant equilibrium states and of asymptotic tracking of output trajectories. Control design for robots with flexible joints takes advantage of the passivity and feedback linearization properties. In robots with flexible links, basic differences arise when controlling the motion at the joint level or at the tip level.

Keywords

Feedback linearization; Gravity compensation; Joint elasticity; Link flexibility; Noncausal and stable inversion; Regulation by motor feedback; Singular perturbation; Vibration damping

Introduction

Robot manipulators are usually considered as rigid multi-body mechanical systems. This ideal assumption simplifies dynamic analysis and control design but may lead to performance degradation and even unstable behavior, due to the excitation of vibrational phenomena.

Flexibility is mainly due to the limited stiffness of transmissions at the joints (Sweet and Good 1985) and to the deflection of slender and lightweight links (Cannon and Schmitz 1984). Joint flexibility is common when motion transmission/reduction elements such as belts, long shafts, cables, harmonic drives, or cycloidal gears are used. Link flexibility is present in large articulated structures, such as very long arms needed for accessing hostile environments (deep sea or space) or automated crane devices for building construction. In both situations, static displacements and dynamic oscillations are introduced between the driving actuators and the actual position of the robot end effector. Undesired vibrations are typically confined beyond the closed-loop control bandwidth, but flexibility cannot be neglected when large speed/acceleration and high accuracy are requested by the task.

In the dynamic modeling, flexibility is assumed concentrated at the robot joints or distributed along the robot links (most of the times with some finite-dimensional approximation). In both cases, additional generalized coordinates are introduced beside those used to describe the rigid motion of the arm in a Lagrangian formulation. As a result, the number of available control inputs is strictly less than the number of degrees of freedom of the mechanical system. This type of under-actuation, though counterbalanced by the presence of additional potential energy helping to achieve system controllability, suggests that the design of satisfactory motion control laws is harder than in the rigid case.

From a control point of view, different design approaches are needed because of structural differences arising between flexible-joint and flexible-link robots. These differences hold for single- or multiple-link robots, in the linear or nonlinear domain, and depend on the physical co-location or not of mechanical flexibility versus control actuation, as well as on the choice of controlled outputs.

In order to measure the state of flexible robots for trajectory tracking control or feedback stabilization purposes, a large variety of sensing devices can be used, including encoders, joint torque sensors, strain gauges, accelerometers, and high-speed cameras. In particular, measuring the full state of the system would require twice the number of sensors than in the rigid case for robots with flexible joints and possibly more for robots with flexible links. The design of controllers that work provably good with a reduced set of measurements is thus particularly attractive.

Robots with Flexible Joints

Dynamic Modeling

A robot with flexible joints is modeled as an open kinematic chain of $n + 1$ rigid bodies, interconnected by n joints undergoing deflection and actuated by n electrical motors. Let $\boldsymbol{\theta}$ be the n-vector of motor (i.e., rotor) positions, as reflected through the reduction gears, and $\boldsymbol{q}$ the n-vector of link positions. The joint deflection is $\boldsymbol{\delta} = \boldsymbol{\theta} - \boldsymbol{q} \not\equiv \boldsymbol{0}$. The standard assumptions are:

A1 Joint deflections $\boldsymbol{\delta}$ are small, limited to the domain of linear elasticity. The elastic torques due to joint deformations are $\boldsymbol{\tau}_J = \boldsymbol{K}(\boldsymbol{\theta} - \boldsymbol{q})$, where $\boldsymbol{K}$ is the positive definite, diagonal joint stiffness matrix.

A2 The rotors of the electrical motors are modeled as uniform bodies having their center of mass on the rotation axis.

A3 The angular velocity of the rotors is due only to their own spinning.

The last assumption, introduced by Spong (1987), is very reasonable for large reduction ratios and also crucial for simplifying the dynamic model.

From the gravity and elastic potential energy, $\mathcal{U} = \mathcal{U}_g + \mathcal{U}_\delta$, and the kinetic energy $\mathcal{T}$ of the robot, applying the Euler-Lagrange equations to the Lagrangian $\mathcal{L} = \mathcal{T} - \mathcal{U}$ and neglecting all dissipative effects leads to the dynamic model

$$M(q)\ddot{q} + n(q, \dot{q}) + K(q - \theta) = 0 \quad (1)$$

$$B\ddot{\theta} + K(\theta - q) = \tau, \quad (2)$$

where $\boldsymbol{M}(\boldsymbol{q})$ is the positive definite, symmetric inertia matrix of the robot links (including the motor masses); $\boldsymbol{n}(\boldsymbol{q}, \dot{\boldsymbol{q}})$ is the sum of Coriolis and centrifugal terms $\boldsymbol{c}(\boldsymbol{q}, \dot{\boldsymbol{q}})$ (quadratic in $\dot{\boldsymbol{q}}$) and gravitational terms $\boldsymbol{g}(\boldsymbol{q}) = (\partial \mathcal{U}_g / \partial \boldsymbol{q})^T$; $\boldsymbol{B}$ is the positive definite, diagonal matrix of motor inertias (reflected through the gear ratios); and $\boldsymbol{\tau}$ are the motor torques (performing work on $\boldsymbol{\theta}$). The inertia matrix of the *complete* system is then $\mathcal{M}(\boldsymbol{q}) = \text{block diag}\{\boldsymbol{M}(\boldsymbol{q}), \boldsymbol{B}\}$. The two n-dimensional second-order differential equations (1) and (2) are referred to as the *link* and the *motor* equations, respectively. When the joint stiffness $\boldsymbol{K} \to \infty$, it is $\boldsymbol{\theta} \to \boldsymbol{q}$ and $\boldsymbol{\tau}_J \to \boldsymbol{\tau}$, so that the two equations collapse in the limit into the standard dynamic model of rigid robots with total inertia $\mathcal{M}(\boldsymbol{q}) = \boldsymbol{M}(\boldsymbol{q}) + \boldsymbol{B}$. On the other hand, when the joint stiffness $\boldsymbol{K}$ is relatively large but still finite, robots with elastic joints show a *two-time-scale* dynamic behavior. A common large scalar factor $1/\epsilon^2 \gg 1$ can be extracted from the diagonal stiffness matrix as $\boldsymbol{K} = \hat{\boldsymbol{K}}/\epsilon^2$. The *slow* subsystem is associated to the link dynamics

$$M(q)\ddot{q} + n(q, \dot{q}) = \tau_J, \quad (3)$$

while the *fast* subsystem takes the form

$$\epsilon^2 \ddot{\boldsymbol{\tau}}_J = \hat{\boldsymbol{K}} \left(\boldsymbol{B}^{-1}(\boldsymbol{\tau} - \boldsymbol{\tau}_J) \right. \\ \left. + \boldsymbol{M}^{-1}(\boldsymbol{q})(\boldsymbol{n}(\boldsymbol{q}, \dot{\boldsymbol{q}}) - \boldsymbol{\tau}_J) \right) \quad (4)$$

For small ϵ, Eqs. (3) and (4) represent a singularly perturbed system. The two separate time scales governing the slow and fast dynamics are t and $\sigma = t/\epsilon$.

Regulation

The basic robotic task of moving between two arbitrary equilibrium configurations is realized by a feedback control law that asymptotically stabilizes the desired robot state.

In the absence of gravity ($\boldsymbol{g} \equiv \boldsymbol{0}$), the equilibrium states are parameterized by the desired reference position $\boldsymbol{q}_d$ of the links and take the

form $q = q_d$, $\theta = \theta_d = q_d$ (with no joint deflection at steady state) and $\dot{q} = \dot{\theta} = 0$. As a result of passivity of the mapping from τ to $\dot{\theta}$, global regulation is achieved by a *decentralized PD* law using only feedback from the motor variables,

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta}, \qquad (5)$$

with diagonal $K_P > 0$ and $K_D > 0$.

In the presence of gravity, the (unique) equilibrium position of the motor associated with a desired link position q_d becomes $\theta_d = q_d + K^{-1}g(q_d)$. Global regulation is obtained by adding an extra gravity-dependent term τ_g to the PD control law (5),

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta} + \tau_g, \qquad (6)$$

with diagonal matrices $K_P > 0$ (at least) and $K_D > 0$. The term τ_g needs to match the gravity load $g(q_d)$ at steady state. The following choices are of slight increasing control complexity, with progressively better transient performance.

- *Constant* gravity compensation: $\tau_g = g(q_d)$. Global regulation is achieved when the smallest positive gain in the diagonal matrix K_P is large enough (Tomei 1991). This sufficient condition can be enforced only if the joint stiffness K dominates the gradient of gravity terms.
- *Online* compensation: $\tau_g = g(\tilde{\theta})$, $\tilde{\theta} = \theta - K^{-1}g(q_d)$. Gravity effects on the links are approximately compensated during robot motion. Global regulation is proven under the same conditions above (De Luca et al. 2005).
- *Quasi-static* compensation: $\tau_g = g(\tilde{q}(\theta))$. At any measured motor position θ, the link position $\tilde{q}(\theta)$ is computed by solving numerically $g(q) + K(q - \theta) = 0$. This removes the need of a strictly positive lower bound on K_P (Kugi et al. 2008), but the joint stiffness should still dominate the gradient of gravity terms.

Additional feedback from the full robot state $(q, \dot{q}, \theta, \dot{\theta})$, measured or reconstructed through dynamic observers, can provide faster and damped transient responses. This solution is particularly convenient when a joint torque sensor measuring τ_J is available (*torque-controlled* robots). Using

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta} + K_T(g(q_d) - \tau_J)$$
$$- K_S\dot{\tau}_J + g(q_d), \qquad (7)$$

the four diagonal gain matrices can be given a special structure so that asymptotic stability is automatically guaranteed (Albu-Schäffer and Hirzinger 2001).

Trajectory Tracking

Let a desired sufficiently smooth trajectory $q_d(t)$ be specified for the robot links over a finite or infinite time interval. The control objective is to asymptotically stabilize the trajectory tracking error $e = q_d(t) - q(t)$ to zero, starting from a generic initial robot state. Assuming that $q_d(t)$ is four times continuously differentiable, a torque input profile $\tau_d(t) = \tau_d(q_d, \dot{q}_d, \ddot{q}_d, \dddot{q}_d, \ddddot{q}_d)$ can be derived from the dynamic model (1) and (2) so as to reproduce exactly the desired trajectory, when starting from matched initial conditions. A local solution to the trajectory tracking problem is provided by the combination of such feedforward term $\tau_d(t)$ with a stabilizing linear feedback from the partial or full robot state; see Eqs. (6) or (7).

When the joint stiffness is large enough, one can take advantage of the system being *singularly perturbed*. A control law τ_s designed for the rigid robot will deal with the slow dynamics, while a relatively simple action τ_f is used to stabilize the fast vibratory dynamics around an invariant manifold associated to the rigid robot control (Spong et al. 1987). This class of composite control laws has the general form

$$\tau = \tau_s(q, \dot{q}, t) + \epsilon\tau_f(q, \dot{q}, \tau_J, \dot{\tau}_J). \qquad (8)$$

When setting $\epsilon = 0$ in Eqs. (3), (4), and (8), the control setup of the equivalent rigid robot is recovered as

$$(M(q) + B)\ddot{q} + n(q, \dot{q}) = \tau_s. \qquad (9)$$

Though more complex, the best performing trajectory tracking controller for the general case is based on *feedback linearization*. Spong (1987) has shown that the nonlinear state feedback

$$\boldsymbol{\tau} = \boldsymbol{\alpha}(\boldsymbol{q}, \dot{\boldsymbol{q}}, \ddot{\boldsymbol{q}}, \dddot{\boldsymbol{q}}) + \boldsymbol{\beta}(\boldsymbol{q})\boldsymbol{v}, \qquad (10)$$

with

$$\begin{aligned}
\boldsymbol{\alpha} =\ & \boldsymbol{M}(\boldsymbol{q})\ddot{\boldsymbol{q}} + \boldsymbol{n}(\boldsymbol{q}, \dot{\boldsymbol{q}}) \\
& + \boldsymbol{B}\boldsymbol{K}^{-1}\left(\left(\ddot{\boldsymbol{M}}(\boldsymbol{q}) + \boldsymbol{K}\right)\ddot{\boldsymbol{q}} + 2\dot{\boldsymbol{M}}(\boldsymbol{q})\dddot{\boldsymbol{q}}\right. \\
& \left. + \ddot{\boldsymbol{n}}(\boldsymbol{q}, \dot{\boldsymbol{q}})\right) \\
\boldsymbol{\beta} =\ & \boldsymbol{B}\boldsymbol{K}^{-1}\boldsymbol{M}(\boldsymbol{q}),
\end{aligned}$$

leads globally to the closed-loop linear system

$$\boldsymbol{q}^{[4]} = \boldsymbol{v}, \qquad (11)$$

i.e., to decoupled chains of four input–output integrators from each auxiliary input v_i to each link position output q_i, for $i = 1, \ldots, n$. The control design is then completed on the linear SISO side, by forcing the trajectory tracking error to be *exponentially stable* with an arbitrary decaying rate. The control law (10) is expressed as a function of the *linearizing coordinates* $(\boldsymbol{q}, \dot{\boldsymbol{q}}, \ddot{\boldsymbol{q}}, \dddot{\boldsymbol{q}})$ (up to the link jerk), which can be however rewritten in terms of the original state $(\boldsymbol{q}, \dot{\boldsymbol{q}}, \boldsymbol{\theta}, \dot{\boldsymbol{\theta}})$ using the dynamic model equations. This fundamental result is the direct extension of the so-called "computed torque" method for rigid robots.

Robots with Flexible Links

Dynamic Modeling

For the dynamic modeling of a single flexible link, the distributed nature of structural flexibility can be captured, under suitable assumptions, by partial differential equations (PDE) with associated boundary conditions. A common model is the *Euler-Bernoulli* beam. The link is assumed to be a slender beam, with uniform geometric characteristics and homogeneous mass distribution, clamped at the base to the rigid hub of an actuator producing a torque τ and rotating on a horizontal plane. The beam is flexible in the lateral direction only, being stiff with respect to axial forces, torsion, and bending due to gravity. Deformations are small and are in the elastic domain. The physical parameters of interest are the linear density ρ of the beam, its flexural rigidity EI, the beam length ℓ, and the hub inertia I_h (with $I_t = I_h + \rho\ell^3/3$). The equations of motion combine lumped and distributed parameter parts, with the hub rotation $\theta(t)$ and the link deformation $w(x, t)$, being $x \in [0, \ell]$ the position along the link. From Hamilton principle, we obtain

$$I_t\,\ddot{\theta}(t) + \rho\int_0^\ell x\,\ddot{w}(x, t)\,dx = \tau(t) \qquad (12)$$

$$EI\,w''''(x, t) + \rho\,\ddot{w}(x, t) + \rho\,x\,\ddot{\theta}(t) = 0 \quad (13)$$

$$\begin{aligned}
w(0, t) &= w'(0, t) = 0, \\
w''(\ell, t) &= w'''(\ell, t) = 0, \qquad (14)
\end{aligned}$$

where a prime denotes partial derivative w.r.t. to space. Equation (14) are the clamped-free boundary conditions at the two ends of the beam (no payload is present at the tip).

For the analysis of this self-adjoint PDE problem, one proceeds by separation of variables in space and time, defining

$$w(x, t) = \phi(x)\delta(t) \qquad \theta(t) = \alpha(t) + k\delta(t), \tag{15}$$

where $\phi(x)$ is the link spatial deformation, $\delta(t)$ is its time behavior, $\alpha(t)$ describes the angular motion of the instantaneous center of mass of the beam, and k is chosen so as to satisfy (12) for $\tau = 0$. Being system (12)–(14) linear, nonrational transfer functions can be derived in the Laplace transform domain between the input torque and some relevant system output, e.g., the angular position of the hub or of the tip of the beam (Kanoh 1990). The PDE formalism provides also a convenient basis for analyzing distributed sensing, feedback from strain sensors (Luo 1993), or even distributed actuation with piezo-electric devices placed along the link.

The transcendental characteristic equation associated to the spatial part of the solution to Eqs. (12)–(14) is

$$I_h \gamma^3 \big(1 + \cos(\gamma \ell) \cosh(\gamma \ell)\big)$$
$$+ \rho \big(\sin(\gamma \ell) \cosh(\gamma \ell) - \cos(\gamma \ell) \sinh(\gamma \ell)\big) = 0. \tag{16}$$

When the hub inertia $I_h \to \infty$, the second term can be neglected and the characteristic equation collapses into the so-called *clamped* condition. Equation (16) has an infinite but countable number of positive real roots γ_i, with associated eigenvalues of resonant frequencies $\omega_i = \gamma_i^2 \sqrt{EI/\rho}$ and orthonormal eigenvectors $\phi_i(x)$, which are the natural deformation shapes of the beam (Barbieri and Özgüner 1988). A finite-dimensional dynamic model is obtained by truncation to a finite number m_e of eigenvalues/shapes. From

$$w(x,t) = \sum_{i=1}^{m_e} \phi_i(x) \delta_i(t) \tag{17}$$

we get

$$I_t \ddot{\alpha}(t) = \tau(t)$$
$$\ddot{\delta}_i(t) + \omega_i^2 \delta_i(t) = \phi_i'(0) \tau(t), \tag{18}$$
$$i = 1, \ldots, m_e,$$

where the rigid body motion (top equation) appears as decoupled from the flexible dynamics, thanks to the choice of variable α rather than θ. Modal damping can be added on the left-hand sides of the lower equations through terms $2\zeta_i \omega_i \dot{\delta}_i$ with $\zeta_i \in [0,1]$. The angular position of the motor hub at the joint is given by

$$\theta(t) = \alpha(t) + \sum_{i=1}^{m_e} \phi_i'(0) \delta_i(t), \tag{19}$$

while the tip angular position is

$$y(t) = \alpha(t) + \sum_{i=1}^{m_e} \frac{\phi_i(\ell)}{\ell} \delta_i(t). \tag{20}$$

The *joint-level* transfer function $p_{\text{joint}}(s) = \theta(s)/\tau(s)$ will always have relative degree two and only minimum phase zeros. On the other hand, the *tip-level* transfer function $p_{\text{tip}}(s) = y(s)/\tau(s)$ will contain non-minimum phase zeros. This basic difference in the pattern of the transmission zeros is crucial for motion control design.

In a simpler modeling technique, a specified class of spatial functions $\phi_i(x)$ is assumed for describing link deformation. The functions need to satisfy only a reduced set of geometric boundary conditions (e.g., *clamped* modes at the link base), but otherwise no dynamic equations of motion such as (13). The use of finite-dimensional expansions like (17) limits the validity of the resulting model to a maximum frequency. This truncation must be accompanied by suitable filtering of measurements and of control commands, so as to avoid or limit spillover effects (Balas 1978).

In the dynamic modeling of robots with n flexible links, the resort to *assumed modes* of link deformation becomes unavoidable. In practice, some form of approximation and a finite-dimensional treatment is necessary. Let $\boldsymbol{\theta}$ be the n-vector of joint variables describing the rigid motion, and $\boldsymbol{\delta}$ be the m-vector collecting the deformation variables of all flexible links. Following a Lagrangian formulation, the dynamic model with clamped modes takes the general form (Book 1984)

$$\begin{pmatrix} \boldsymbol{M}_{\theta\theta}(\boldsymbol{\theta}, \boldsymbol{\delta}) & \boldsymbol{M}_{\theta\delta}(\boldsymbol{\theta}, \boldsymbol{\delta}) \\ \boldsymbol{M}_{\theta\delta}^T(\boldsymbol{\theta}, \boldsymbol{\delta}) & \boldsymbol{M}_{\delta\delta}(\boldsymbol{\theta}, \boldsymbol{\delta}) \end{pmatrix} \begin{pmatrix} \ddot{\boldsymbol{\theta}} \\ \ddot{\boldsymbol{\delta}} \end{pmatrix}$$
$$+ \begin{pmatrix} \boldsymbol{n}_{\theta}(\boldsymbol{\theta}, \boldsymbol{\delta}, \dot{\boldsymbol{\theta}}, \dot{\boldsymbol{\delta}}) \\ \boldsymbol{n}_{\delta}(\boldsymbol{\theta}, \boldsymbol{\delta}, \dot{\boldsymbol{\theta}}, \dot{\boldsymbol{\delta}}) \end{pmatrix} + \begin{pmatrix} \boldsymbol{0} \\ \boldsymbol{D}\dot{\boldsymbol{\delta}} + \boldsymbol{K}\boldsymbol{\delta} \end{pmatrix} = \begin{pmatrix} \boldsymbol{\tau} \\ \boldsymbol{0} \end{pmatrix}, \tag{21}$$

where the positive definite, symmetric inertia matrix $\mathcal{M}$ of the complete robot and the Coriolis, centrifugal, and gravitational terms $\boldsymbol{n}$ have been partitioned in blocks of suitable dimensions, $\boldsymbol{K} > 0$ and $\boldsymbol{D} \geq 0$ are the robot link stiffness and damping matrices, and $\boldsymbol{\tau}$ is the n-vector of actuating torques.

F

The dynamic model (21) shows the general couplings existing between nonlinear rigid body motion and linear flexible dynamics. In this respect, the linear model (18) of a single flexible link is a remarkable exception.

The choice of specific assumed modes may simplify the blocks of the robot inertia matrix, e.g., orthonormal modes used for each link induce a decoupled structure of the diagonal inertia subblocks of $M_{\delta\delta}$. Quite often the total kinetic energy of the flexible robot is evaluated only in the undeformed configuration $\delta = 0$. With this approximation, the inertia matrix becomes independent of δ, and so the velocity terms in the model. Furthermore, due to the hypothesis of small deformation of each link, the dependence of the gravity term in the lower component n_δ is only a function of θ.

The validation of (21) goes through the experimental identification of the relevant dynamic parameters. Besides those inherited from the rigid case (mass, inertia, etc.), also the set of structural resonant frequencies and associated deformation profiles should be identified.

Control of Joint-Level Motion

When the target variables to be controlled are defined at the joint level, the control problem for robots with flexible links is similar to that of robots with flexible joints. As a matter of fact, the models (1), (2), and (21) are both *passive* systems with respect to the output θ; see (19) in the scalar case. For instance, regulation is achieved by a PD action with constant gravity compensation, using a control law of the form (6) without the need of feeding back link deformation variables (De Luca and Siciliano 1993a). Similarly, stable tracking of a joint trajectory $\theta_d(t)$ is obtained by a singular perturbation control approach, with flexible modes dynamics acting at multiple time scales with respect to rigid body motion (Siciliano and Book 1988), or by an inversion-based control (De Luca and Siciliano 1993b), where input–output (rather than full state) exact linearization is realized and the effects of link flexibility are canceled on the motion of the robot joints. While vibrational behavior will still affect the robot at the level of end-effector motion, the closed-loop dynamics of the δ variables is stable and link deformations converge to a steady-state constant value (zero in the absence of gravity) thanks to the intrinsic damping of the mechanical structure. Improved transients are indeed obtained by active modal damping control (Cannon and Schmitz 1984).

A control approach specifically developed for the rest-to-rest motion of flexible mechanical systems is *command shaping* (Singer and Seering 1990). The original command designed to achieve a desired motion for a rigid robot is convolved with suitable signals delayed in time, so as to cancel (or reduce to a minimum) the effects of the excited vibration modes at the time of motion completion. For a single slewing link with linear dynamics, as in (18), the rest-to-rest input command is computed in closed form by using impulsive signals and can be made robust via an over-parameterization.

Control of Tip-Level Motion

The design of a control law that allows asymptotic tracking of a desired trajectory for the end effector of a robot with flexible links needs to face the unstable zero dynamics associated to the problem. In the linear case of a single flexible link, this is equivalent to the presence of non-minimum phase zeros in the transfer function to the tip output (20). Direct inversion of the input–output map leads to instability, due to cancellation of non-minimum phase zeros by unstable poles, with link deformation growing unbounded and control saturations.

The solution requires instead to determine the unique reference state trajectory of the flexible structure that is associated to the desired tip trajectory and has *bounded* deformation. Based on regulation theory, the control law will be the superposition of a nominal feedforward action, which keeps the system along the reference state trajectory (and thus the output on the desired trajectory), and of a stabilizing feedback that reduces the error with respect to this state trajectory to zero without resorting to dangerous cancellations.

In general, computing such a control law requires the solution of a set of nonlinear partial

differential equations. However, in the case of a single flexible link with linear dynamics, the feedforward profile is simply derived by an inversion defined in the *frequency domain* (Bayo 1987). The desired tip acceleration $\ddot{y}_d(t)$, $t \in [0, T]$, is considered as part of a rest-to-rest periodic signal, with zero mean value and zero integral. The procedure, implemented efficiently using Fast Fourier Transform on discrete-time samples, will automatically generate bounded time signals only. The resulting unique torque profile $\tau_d(t)$ will be a *noncausal* command, anticipating the actual start of the output trajectory at $t = 0$ (so as to *precharge* the link to the correct initial deformation) and ending after $t = T$ (to *discharge* the residual link deformation and recover the final rest configuration).

The same result was recovered by Kwon and Book (1994) in the time domain, by forward integrating in time the stable part of the inverse system dynamics and backward integrating the unstable part. An extension to the multi-link non-linear case uses an iterative approach on repeated linear approximations of the system along the nominal trajectory (Bayo et al. 1989).

Summary and Future Directions

The presence of mechanical flexibility in the joints and the links of multi-dof robots poses challenging control problems. Control designs take advantage or are limited by some system-level properties. Robots with flexible joints are passive systems at the level of motor outputs, have no zero dynamics associated to the link position outputs, and are always feedback linearizable systems. Robots with flexible links are still passive for joint-level outputs, but cannot be feedback linearized in general, and have unstable zero dynamics (non-minimum phase zeros in the linear case) when considering the end-effector position as controlled output.

State-of-the-art control laws address regulation and trajectory tracking tasks in a satisfactory way, at least in nominal conditions and under full-state feedback. Current research directions are aimed at achieving robustness to model uncertainties and external disturbances (with adaptive, learning, or iterative schemes), and further exploit the design of control laws under limited measurements and noisy sensing. Beyond free motion tasks, an accurate treatment of interaction tasks with the environment, requiring force or impedance controllers, is still missing for flexible robots. In this respect, passivity-based control approaches that do not necessarily operate dynamic cancellations may take advantage of the existing compliance, trading off between improved energy efficiency and some reduction in nominal performance.

Often seen as a limiting factor for performance, the presence of joint elasticity is now becoming an explicit advantage for safe physical human-robot interaction and for locomotion. Next generation lightweight robots and humanoids will use flexible joints and also compact actuation with online controlled variable joint stiffness, an area of active research.

Flocking in Networked Systems

Ali Jadbabaie
University of Pennsylvania, Philadelphia, PA, USA

Abstract

Flocking is a collective behavior exhibited by many animal species such as birds, insects, and fish. Such behavior is generated by distributed motion coordination through nearest-neighbor interactions. Empirical study of such behavior has been an active research in ecology and evolutionary biology. Mathematical study of such behaviors has become an active research area in a diverse set of disciplines, ranging from statistical physics and computer graphics to control theory, robotics, opinion dynamics in social networks, and general theory of multiagent systems. While models vary in detail, they are all based on local diffusive dynamics that results in emergence of consensus in direction of motion. Flocking is closely related to the notion of consensus and synchronization in multiagent systems, as examples of collective phenomena that emerge in multiagent systems as result of local nearest-neighbor interactions.

Keywords

Consensus; Dynamics; Flocking; Graph theory; Markov chains; Switched dynamical systems; Synchronization

Flocking or social aggregation is a group behavior observed in many animal species, ranging

from various types of birds to insects and fish. The phenomena can be loosely defined as any aggregate collective behavior in parallel rectilinear formation or (in case of fish) in collective circular motion. The mechanisms leading to such behavior have been (and continues to be) an active area of research among ecologists and evolutionary biologists, dating back to the 1950s if not earlier. The engineering interest in the topic is much more recent.

In 1986, Craig Reynolds (1987), a computer graphics researcher, developed a computer model of collective behavior for animated artificial objects called boids. The flocking model for boids was used to realistically duplicate aggregation phenomena in fish flocks and bird schools for computer animation. Reynolds developed a simple, intuitive physics-based model: each boid was a point mass subject to three simple steering forces: alignment (to steer each boid towards the average heading of its *local* flockmates), cohesion (steering to move towards the average position of *local* flockmates), and separation (to avoid crowding local flockmates). The term local should be understood as those flockmates who are within each other's influence zone, which could be a disk (or a wide-angle sector of a disk) centered at each boid with a prespecified radius. This simple zone-based model created very realistic flocking behaviors and was used in many animations (Fig. 1). Reynolds' 3 rules of flocking.

Nine years later, in 1995, Vicsek et al. (1995) and coauthors independently developed a model for velocity alignment of self-propelled particles (SPPs) in a square with periodic boundary conditions. SPPs are essentially kinematic particles moving with constant speed and the steering law determines the angle of (what control theorists call a kinematic, nonholonomic vehicle model). Vicsek et al.'s steering law was very intuitive and simple and was essentially Reynolds' zone-based alignment rule (Vicsek was not aware of Reynolds' result): each particle averages the *angle* of its velocity vector with that of its neighbors (those within a disk of a prespecified distance), plus a noise term used to model inaccuracies in averaging. Once the velocity vector is determined at each time, each particle takes a unit step along that direction, then determining its neighbors again and repeating the protocol.

The simulations were done in a square of unit length with periodic boundary conditions, to simulate infinite space. Vicsek and coauthors simulated this behavior and found that as the density of the particles increased, a preferred direction spontaneously emerged, resulting in a global group behavior with nearly aligned velocity vectors for all particles, despite the fact that the update protocol is entirely local.

With the interest in control theory shifting towards multiagent systems and networked coordination and control, it became clear that the mathematics of how birds flock and fish school and how individuals in a social network reach agreement (even though they are often only influenced by other like-minded individuals) are quite related to the question of how can one engineer a swarm of robots to behave like bird flocks.
Flocking in Networked Systems, Fig. 1 Photo from http://red3d.com/cwr/boids/

These questions have occupied the minds of many researchers in diverse areas ranging from control theory to robotics, mathematics, and computer science. As discussed above, most of the early research, which happened in computer graphics and statistical physics, was on modeling and simulation of collective behavior. Over the past 13 years, however, the focus has shifted to rigorous systems theoretic foundations, leading to what one might call a theory of collective phenomena in multiagent systems. This theory blends dynamical systems, graph theory, Markov chains, and algorithms.

This type of collective phenomena are often modeled as many-degrees-of-freedom (discrete-time or continuous-time) dynamical systems with an additional twist that the interconnection structure between individual dynamical systems changes, since the motion of each node in a flock (or opinion of an individual) is affected primarily by those in each node's *local neighborhood*. The twist here is that the local neighborhood is not fixed: neighbors are defined based on the actual state of the system, for example, in case of Vicsek's alignment rule, as each particle averages its velocity direction with that of its neighbors and then takes a step, the set of its nearest neighbors can change.

Interestingly, very similar models were developed in statistics and mathematical sociology literature to describe how individuals in a social network update their opinions as a function of the opinion of their friends. The first such model goes back to the seminal work of DeGroot (1974) in 1974. DeGroot's model simply described the evolution of a group's scalar opinion as a function of the opinion of their neighbors by an iterative averaging scheme that can be conveniently modeled as a Markov chain. Individuals are represented by nodes of a graph, start from an opinion at time zero, and then are influenced by the people in their social clique. In DeGroot's model though, the network is given exogenously and does not change as a function of the opinions. The model therefore can be analyzed using the celebrated Perron-Frobenius theorem. The evolution of opinions is a discrete dynamic system that corresponds to an averaging map. When the network is fixed and connected (i.e., there is a path from every node to every other node) and agents also include their own opinions in the averaging, the update results in computation of a global weighted average of initial opinions, where the weight of each initial opinion in the final aggregate is proportional to the "importance" of each node in the network.

The flocking models of Reynolds (1987) and Vicsek et al. (1995), however, have an extra twist: the network changes as opinions are updated. Similarly, more refined sociological models developed over the past decade also capture this endogeneity (Hegselmann and Krause 2002): each individual agent is influenced by others only when their opinion is close to her own. In other words, as opinions evolve, neighborhood structures change as the function of the evolving opinion, resulting in a switched dynamical system in which switching is state dependent.

In a paper in 2003, Jadbabaie and coauthors (2003) studied the Reynolds' alignment rule in the context of Vicsek's model when there is no exogenous noise. To model the endogeneity of the change in neighborhood structure, they developed a model based on repeated local averaging in which the neighborhood structure changes over time and therefore instead of a simple discrete-time linear dynamical system, the model is a discrete linear inclusion or a switched linear system. The question of interest was to determine what regimes of network changes could result in flocking. Clearly, as also DeGroot's model suggests, when the local neighbor structures do not change, connectivity is the key factor for flocking. This is a direct consequence of Perron-Frobenius theory. The result can also be described in terms of directed graphs. What is the equivalent condition in changing networks? Jadbabaie and coauthors show in their paper that indeed connectivity is important, but it need not hold every time: rather, there needs to be time periods over which the graphs are *connected in time*. More formally, the process of neighborhood changes due to motion in Vicsek's model can be simply abstracted as a graph in which the links "blink" on and off. For flocking, one needs to ensure that there are

time periods over which the union of edges (that occur as a result of proximity of particles) needs to correspond to a connected graph and such intervals need to occur infinitely often. It turns out that many of these ideas were developed much earlier in a thesis and following paper by Tsitsiklis (1984) and Tsitsiklis et al. (1986), in the context of distributed and asynchronous computation of global averages in changing graphs, and in a paper by Chatterjee and Seneta (1977), in the context of nonhomogeneous Markov chains. The machinery for proving such a results, however, is classical and has a long history in the theory of inhomogeneous Markov chains, a subject studied since the time of Markov himself, followed by Birkhoff and other mathematicians such as Hajnal, Dobrushin, Seneta, Hatfield, Daubachies, and Lagarias, to name a few.

The interesting twist in analysis of Vicsek's model is that the Euclidean norm of the distance to the globally converged "consensus angle" (or consensus opinion in the case of opinion models) can actually *grow* in a single step of the process; therefore, standard quadratic Lyapunov function arguments which serve as the main tool for analysis of switched linear systems are not suitable for the analysis of such models. However, it is fairly easy to see that under the process of local averaging, the largest value cannot increase and the smallest value cannot decrease. In fact, one can show that if enough connected graphs occur as the result of the switching process, the maximum value will be strictly decreasing and the minimum value will be strictly increasing The paper by Jadbabaie and coauthors (2003) has lead to a flurry of results in this area over the past decade. One important generalization to the results of Jadbabaie et al. (2003), Tsitsiklis (1984), and Tsitsiklis et al. (1986) came 2 years later in a paper by Moreau (2005), who showed that these results can be generalized to nonlinear updates and directed graphs. Moreau showed that any dynamic process that assigns a point in the interior of the convex hull of the value of each node and its neighbors will eventually result in agreement and consensus, if and only if the union of graphs from every time step till infinity

contains a directed spanning tree (a node who has direct links to every other node).

Some of these results were also extended to the analysis of the Reynolds' model of flocking including the other two behaviors. First, Tanner and coauthors (2003, 2007) showed in a series of papers in 2003 and 2007 that a zone-based model similar to Reynolds can result in flocking for dynamic agents, provided that the graph representing interagent communications stays connected. Olfati-Saber and coauthors (2007) developed similar results with a slightly different model.

Many generalizations and extension for these results exist in a diverse set of disciplines, resulting in a rich theory which has had applications from robotics (such as rendezvous in mobile robots) (Cortés et al. 2006) to mathematical sociology (Hegselmann and Krause 2002) and from economics (Golub and Jackson 2010) to distributed optimization theory (Nedic and Ozdaglar 2009). However, some of the fundamental mathematical questions related to flocking still remain open.

First, most results focus on endogenous models of network change. A notable extension is a paper by Cucker and Smale (2007), in which the authors develop and analyze an endogenous model of flocking that cleverly *smoothens out* the discontinuous change in network structure by allowing each node's influence to decay smoothly as a function of distance.

Recently, in a series of papers, Chazelle has made progress in this arena by using tools from computational geometry and algorithms for analysis of endogenous models of flocking (Chazelle 2012). Chazelle has introduced the notion of the *s-energy* of a flock, which can be thought of as a parameterized family of Lyapunov functions that represent the evolution of global misalignment between flockmates. Via tools from dynamical systems, computational geometry, combinatorics, complexity theory, and algorithms, Chazelle creates an "algorithmic calculus," for *diffusive influence systems:* surprisingly, he shows that the orbit or flow of such systems is attracted to a fixed point in the case of undirected graphs and a limit cycle for almost all arbitrarily small random

perturbations. Furthermore, the convergence time can also be bounded in both cases and the bounds are essentially optimal. The setup of the diffusive influence system developed by Chazelle creates a near-universal setup for analyzing various problems involving collective behavior in networked multiagent systems, from flocking, opinion dynamics, and information aggregation to synchronization problems.

To make further progress on analysis of what one might call networked dynamical systems (which Chazelle calls influences systems), one needs to combine mathematics of algorithms, complexity, combinatorics, and graphs with systems theory and dynamical systems.

Summary and Future Directions

This article presented a brief summary of the literature on flocking and distributed motion co-ordination. Flocking is the process by which various species exhibit synchronous collective motion from simple local interaction rules. Motivated by social aggregation in various species, various algorithms have been developed in the literature to design distributed control laws for group behavior in collective robotics and analysis of opinion dynamics in social networks. The models describe each agent as a kinematic or point mass particle that aligns each agent's direction with that of its neighbors using repeated local averaging of directions. Since the neighborhood structures change due to motion, this results in a distributed switched dynamical system. If a weak notion of connectivity among agents is preserved over time, then agents reach consensus in their direction of motion. Despite the flurry of results in this area, the analysis of this phenomenon that accounts for endogenous change in dynamics is for the most part open.

Force Control in Robotics

Luigi Villani
Dipartimento di Ingeneria Elettrica e Tecnologie
dell'Informazione, Università degli Studi di
Napoli Federico II, Napoli, Italy

Abstract

Force control is used to handle the physical inter-
action between a robot and the environment and
also to ensure safe and dependable operation in
the presence of humans. The control goal may be
that to keep the interaction forces limited or that
to guarantee a desired force along the directions
where interaction occurs while a desired motion
is ensured in the other directions. This entry
presents the basic control schemes, focusing on
robot manipulators.

Keywords

Compliance control; Constrained motion;
Force control; Force/torque sensor; Hybrid
force/motion control; Impedance control;
Stiffness control

Introduction

Control of the physical interaction between
a robot manipulator and the environment is
crucial for the successful execution of a number
of practical tasks where the robot end effector
has to manipulate an object or perform some
operation on a surface. Typical examples in
industrial settings include polishing, deburring,
machining, or assembly.

During contact, the environment may set con-
straints on the geometric paths that can be fol-
lowed by the robot's end effector (kinematic
constraints) as in the case of sliding on a rigid
surface. In other situations, the interaction occurs
with a dynamic environment as in the case of

collaboration with a human. In all cases, a pure
motion control strategy is not recommended, es-
pecially if the environment is stiff.

The higher the environment stiffness and po-
sition control accuracy are, the more easily the
contact forces may rise and reach unsafe values.
This drawback can be overcome by introducing
compliance, either in a passive or in an active
fashion, to accommodate the robot motion in
response to interaction forces.

Passive compliance may be due to the struc-
tural compliance of the links, joints, and end ef-
fector or to the compliance of the position servo.
Soft robot arms with elastic joints or links are
purposely designed for intrinsically safe interac-
tion with humans. In contrast, active compliance
is entrusted to the control system, denoted *inter-
action control* or *force control*. In same cases, the
measurement of the contact force and moment
is required, which is fed back to the controller
and used to modify or even generate online the
desired motion of the robot (Whitney 1977).

The passive solution is faster than active re-
action commanded by a computer control algo-
rithm. However, the use of passive compliance
alone lacks of flexibility and cannot guarantee
that high contact forces will never occur. Hence,
the most effective solution is that of using ac-
tive force control (with or without force feed-
back) in combination with some degree of passive
compliance.

In general, six force components are required
to provide complete contact force information:
three translational force components and three
torques. Often, a *force/torque sensor* is mounted
at the robot wrist (see an example in Fig. 1),
but other possibilities exist, for example, force
sensors can be placed on the fingertips of robotic
hands; also, external forces and moments can be
estimated via shaft torque measurements of joint
torque sensors.

The force control strategies can be grouped
into two categories (Siciliano and Villani 1999):
those performing indirect force control and those
performing direct force control. The main dif-
ference between the two categories is that the
former achieve force control via motion control,

$$\mathbf{v}_e = \mathbf{J}(\boldsymbol{q})\dot{\boldsymbol{q}} .$$

The matrix $\mathbf{J}$ is the end-effector Jacobian. For simplicity, the case of nonredundant nonsingular manipulators is considered; therefore, the Jacobian is a square nonsingular matrix.

The force $\boldsymbol{f}_e$ and moment $\boldsymbol{m}_e$ applied by the end effector to the environment are the components of the wrench $\boldsymbol{h}_e = (\boldsymbol{f}_e^T \quad \boldsymbol{m}_e^T)^T$. The joint torques $\boldsymbol{\tau}$ corresponding to $\boldsymbol{h}_e$ can be computed as

$$\boldsymbol{\tau} = \mathbf{J}^T(\boldsymbol{q})\boldsymbol{h}_e .$$

It is useful to consider the operational space formulation of the dynamic model of a rigid robot manipulator in contact with the environment (Khatib 1987):

$$\boldsymbol{\Lambda}(\boldsymbol{q})\dot{\mathbf{v}}_e + \boldsymbol{\Gamma}(\boldsymbol{q}, \dot{\boldsymbol{q}})\mathbf{v}_e + \boldsymbol{\eta}(\boldsymbol{q}) = \boldsymbol{h}_c - \boldsymbol{h}_e , \quad (1)$$

where $\boldsymbol{\Lambda}(\boldsymbol{q})$ is the 6×6 operational space inertia matrix, $\boldsymbol{\Gamma}(\boldsymbol{q}, \dot{\boldsymbol{q}})$ is the wrench including centrifugal and Coriolis effects, and $\boldsymbol{\eta}(\boldsymbol{q})$ is the wrench of the gravitational effects. The vector $\boldsymbol{h}_c = \mathbf{J}^{-T}\boldsymbol{\tau}$ is the equivalent end-effector wrench corresponding to the input joint torques $\boldsymbol{\tau}_c$.

Equation (1) can be seen as a representation of the Newton's Second Law of Motion where all the generalized forces acting on the joints of the robot are reported at the end effector.

The full specification of the system dynamics would require also the analytic description of the interaction force and moment $\boldsymbol{h}_e$. This is a very demanding task from a modeling viewpoint.

The design of the interaction control and the performance analysis are usually carried out under simplifying assumptions. The following two cases are considered:

1. The robot is perfectly rigid, all the compliance in the system is localized in the environment, and the contact wrench is approximated by a linear elastic model.
2. The robot and the environment are perfectly rigid and purely kinematics constraints are imposed by the environment.

It is obvious that these situations are only ideal. However, the robustness of the control should be able to cope with situations where some of the

Force Control in Robotics, Fig. 1 Industrial robot with wrist force/torque sensor and deburring tool

without explicit closure of a force feedback loop; the latter instead offer the possibility of controlling the contact force and moment to a desired value, thanks to the closure of a force feedback loop.

Modeling

The case of interaction of the end effector of a robot manipulator with the environment is considered, which is the most common situation in industrial applications.

The end-effector pose can be represented by the position vector $\boldsymbol{p}_e$ and the rotation matrix $\mathbf{R}_e$, corresponding to the position and orientation of a frame attached to the end effector with respect to a fixed-base frame.

The end-effector velocity is denoted by the 6×1 twist vector $\mathbf{v}_e = (\dot{\boldsymbol{p}}_e^T \quad \boldsymbol{\omega}_e^T)^T$ where $\dot{\boldsymbol{p}}_e$ is the translational velocity and $\boldsymbol{\omega}_e$ is the angular velocity and can be computed from the joint velocity vector $\dot{\boldsymbol{q}}$ using the linear mapping

ideal assumptions are relaxed. In that case the control laws may be adapted to deal with nonideal characteristics.

Indirect Force Control

The aim of indirect force control is that of achieving a desired compliant dynamic behavior of the robot's end effector in the presence of interaction with the environment.

Stiffness Control

The simpler approach is that of imposing a suitable static relationship between the deviation of the end-effector position and orientation from a desired pose and the force exerted on the environment, by using the control law

$$\mathbf{h}_c = \mathbf{K}_P \Delta \mathbf{x}_{de} - \mathbf{K}_D \mathbf{v}_e + \boldsymbol{\eta}(\mathbf{q}) , \qquad (2)$$

where $\mathbf{K}_P$ and $\mathbf{K}_D$ are suitable matrix gains and $\Delta \mathbf{x}_{de}$ is a suitable error between a desired and the actual end-effector position and orientation. The position error component of $\Delta \mathbf{x}_{de}$ can be simply chosen as $\mathbf{p}_d - \mathbf{p}_e$. Concerning the orientation error component, different choices are possible (Caccavale et al. 1999), which are not all equivalent, but this issue is outside the scope of this entry.

The control input (2) corresponds to a wrench (force and moment) applied to the end effector, which includes a gravity compensation term $\boldsymbol{\eta}(\mathbf{q})$, a viscous damping term $\mathbf{K}_D \mathbf{v}_e$, and an elastic wrench provided by a virtual spring with stiffness matrix $\mathbf{K}_P$ (or, equivalently, compliance matrix $\mathbf{K}_P^{-1}$) connecting the end-effector frame with a frame of desired position and orientation. This control law is known as *stiffness control* or *compliance control* (Salisbury 1980).

Using the Lyapunov method, it is possible to prove the asymptotic stability of the equilibrium solution of equation

$$\mathbf{K}_P \Delta \mathbf{x}_{de} = \mathbf{h}_e ,$$

meaning that, at steady state, the robot's end effector has a desired elastic behavior under the action of the external wrench $\mathbf{h}_e$. It is clear that, if $\mathbf{h}_e \neq \mathbf{0}$, then the end effector deviates from the desired pose, which is usually denoted as *virtual pose*.

Physically, the closed-loop system (1) with (2) can be seen as a 6-DOF nonlinear and configuration-dependent mass-spring-damper system with inertia (mass) matrix $\boldsymbol{\Lambda}(\mathbf{q})$ and adjustable damping $\mathbf{K}_D$ and stiffness $\mathbf{K}_P$, under the action of the external wrench $\mathbf{h}_e$.

Impedance Control

A configuration-independent dynamic behavior can be achieved if the measure of the end-effector force and moment $\mathbf{h}_e$ is available, by using the control law, known as *impedance control* (Hogan 1985):

$$\mathbf{h}_c = \boldsymbol{\Lambda}(\mathbf{q})\boldsymbol{\alpha} + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \boldsymbol{\eta}(\mathbf{q}) + \mathbf{h}_e ,$$

where $\boldsymbol{\alpha}$ is chosen as:

$$\boldsymbol{\alpha} = \dot{\mathbf{v}}_d + \mathbf{K}_M^{-1}(\mathbf{K}_D \Delta \mathbf{v}_{de} + \mathbf{K}_P \Delta \mathbf{x}_{de} - \mathbf{h}_e) .$$

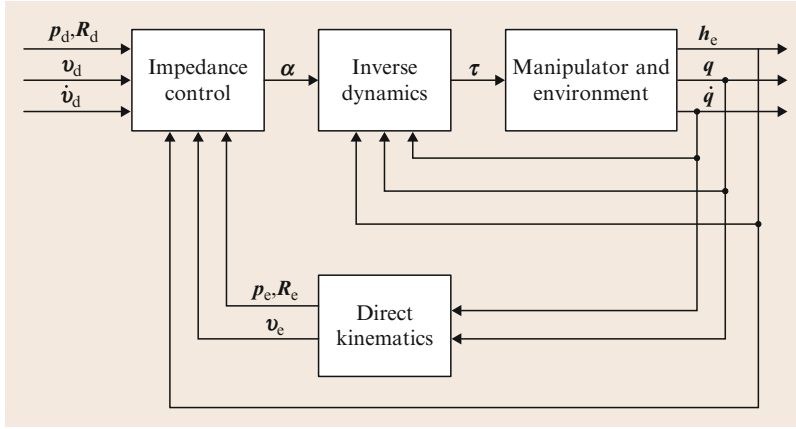
The following expression can be found for the closed-loop system

$$\mathbf{K}_M \Delta \dot{\mathbf{v}}_{de} + \mathbf{K}_D \Delta \mathbf{v}_{de} + \mathbf{K}_P \Delta \mathbf{x}_{de} = \mathbf{h}_e , \qquad (3)$$

representing the equation of a 6-DOF configuration-independent mass-spring-damper system with adjustable inertia (mass) matrix $\mathbf{K}_M$, damping $\mathbf{K}_D$, and stiffness $\mathbf{K}_P$, known as mechanical *impedance*.

A block diagram of the resulting impedance control is sketched in Fig. 2.

The selection of good impedance parameters ensuring a satisfactory behavior is not an easy task and can be simplified under the hypothesis that all the matrices are diagonal, resulting in a decoupled behavior for the end-effector coordinates.

Moreover, the dynamics of the controlled system during the interaction depends on the dynamics of the environment that, for simplicity, can be approximated as a simple elastic law for each coordinate, of the form


Force Control in Robotics, Fig. 2 Impedance control

$$h_e = k\Delta x_{eo} \; ,$$

where $\Delta x_{eo} = x_e - x_o$, while x_o and k are the undeformed position and the stiffness coefficient of the spring, respectively.

In the above hypotheses, the transient behavior of each component of Eq. (3) can be set by assigning the natural frequency and damping ratio with the relations

$$\omega_n = \sqrt{\frac{k_P + k}{k_M}} \; , \quad \zeta = \frac{1}{2}\frac{k_D}{\sqrt{k_M(k_P + k)}} \; .$$

Hence, if the gains are chosen so that a given natural frequency and damping ratio are ensured during the interaction (i.e., for $k \neq 0$), a smaller natural frequency with a higher damping ratio will be obtained when the end effector moves in free space (i.e., for $k = 0$). As for the steady-state performance, the end-effector error and the interaction force for the generic component are

$$\Delta x_{de} = \frac{k}{(k_P + k)}\Delta x_{do} \; , \quad h = \frac{k_P k}{k_P + k}\Delta x_{do} \; ,$$

showing that, during interaction, the contact force can be made small at the expense of a large position error in steady state, as long as the robot stiffness k_P is set low with respect

to the stiffness of the environment k and vice versa.

Direct Force Control

Indirect force control does not require explicit knowledge of the environment, although to achieve a satisfactory dynamic behavior, the control parameters have to be tuned for a particular task. On the other hand, a model of the interaction task is usually required for the synthesis of direct force control algorithms.

In the following, it is assumed that the environment is rigid and frictionless and imposes kinematic constraints to the robot's end-effector motion (Mason 1981). These constraints reduce the dimension of the space of the feasible end-effector velocities and of the contact forces and moments. In detail, in the presence of m independent constraints ($m < 6$), the end-effector velocity belongs to a subspace of dimension $6 - m$, while the end-effector wrench belongs to a subspace of dimension m and can be expressed in the form

$$\mathbf{v}_e = \mathbf{S}_v(\mathbf{q})\mathbf{\nu} \; , \quad \mathbf{h}_e = \mathbf{S}_f(\mathbf{q})\mathbf{\lambda}$$

where $\mathbf{\nu}$ is a suitable $(6 - m) \times 1$ vector and $\mathbf{\lambda}$ is a suitable $m \times 1$ vector. Moreover, the subspaces of forces and velocity are *reciprocal*, i.e.:

$$\boldsymbol{h}_{\mathrm{e}}^{T}\mathbf{v}_{\mathrm{e}} = 0\,, \quad \mathbf{S}_{\mathrm{f}}^{T}(\boldsymbol{q})\mathbf{S}_{\mathrm{v}}(\boldsymbol{q}) = \mathbf{0}\,.$$

The concept of reciprocity expresses the physical fact that, in the hypothesis of rigid and frictionless contact, the wrench does not cause any work against the twist.

An interaction task can be assigned in terms of a desired end-effector twist $\mathbf{v}_{\mathrm{d}}$ and wrench $\boldsymbol{h}_{\mathrm{d}}$ that are computed as:

$$\mathbf{v}_{\mathrm{d}} = \mathbf{S}_{\mathrm{v}}\boldsymbol{v}_{\mathrm{d}}\,, \quad \boldsymbol{h}_{\mathrm{d}} = \mathbf{S}_{\mathrm{f}}\boldsymbol{\lambda}_{\mathrm{d}}\,,$$

by specifying vectors $\boldsymbol{\lambda}_{\mathrm{d}}$ and $\boldsymbol{v}_{\mathrm{d}}$.

In many robotic tasks it is possible to set an orthogonal reference frame, usually referred as *task frame* (De Schutter and Van Brussel 1988), in which the matrices $\mathbf{S}_{\mathrm{v}}$ and $\mathbf{S}_{\mathrm{f}}$ are constant. Moreover, the interaction task is specified by assigning a desired force/torque or a desired linear/angular velocity along/about each of the frame axes.

An example of task frame definition and task specification is given below.

Peg-in-Hole: The goal of this task is to push the peg into the hole while avoiding wedging and jamming. The peg has two degrees of motion freedom; hence, the dimension of the velocity-controlled subspace is $6 - m = 2$, while the dimension of the force-controlled subspace is $m = 4$. The task frame can be chosen as shown in Fig. 3, and the task can be achieved by assigning the following desired forces and torques:

- Zero forces along the x_{t} and y_{t} axes
- Zero torques about the x_{t} and y_{t} axes and the desired velocities
- A nonzero linear velocity along the z_{t}-axis
- An arbitrary angular velocity about the z_{t}-axis

The task continues until a large reaction force in the z_{t} direction is measured, indicating that the peg has hit the bottom of the hole, not represented in the figure. Hence, the matrices $\mathbf{S}_{\mathrm{f}}$ and $\mathbf{S}_{\mathrm{v}}$ can be chosen as

$$\mathbf{S}_{\mathrm{f}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}\,, \quad \mathbf{S}_{\mathrm{v}} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}\,.$$
Force Control in Robotics, Fig. 3 Insertion of a cylindrical peg into a hole

The task frame can be chosen attached either to the end effector or to the environment.

Hybrid Force/Motion Control

The reciprocity of the velocity and force subspaces naturally leads to a control approach, known as *hybrid force/motion control* (Raibert and Craig 1981; Yoshikawa 1987), aimed at controlling simultaneously both the contact force and the end-effector motion in two reciprocal subspaces.

The reduced order dynamics of the robot with kinematic constraints is described by $6 - m$ second-order equations

$$\boldsymbol{\Lambda}_{\mathrm{v}}(\boldsymbol{q})\dot{\boldsymbol{v}} = \mathbf{S}_{\mathrm{v}}^{T}\big[\boldsymbol{h}_{\mathrm{c}} - \boldsymbol{\mu}(\boldsymbol{q},\dot{\boldsymbol{q}})\big]\,,$$

where $\boldsymbol{\Lambda}_{\mathrm{v}} = \mathbf{S}_{\mathrm{v}}^{T}\boldsymbol{\Lambda}\mathbf{S}_{\mathrm{v}}$ and $\boldsymbol{\mu}(\boldsymbol{q},\dot{\boldsymbol{q}}) = \boldsymbol{\Gamma}(\boldsymbol{q},\dot{\boldsymbol{q}})\mathbf{v}_{\mathrm{e}} + \boldsymbol{\eta}(\boldsymbol{q})$, assuming constant matrices $\mathbf{S}_{\mathrm{v}}$ and $\mathbf{S}_{\mathrm{f}}$. Moreover, the vector $\boldsymbol{\lambda}$ can be computed as

$$\boldsymbol{\lambda} = \mathbf{S}_{\mathrm{f}}^{\dagger}(\boldsymbol{q})\big[\boldsymbol{h}_{\mathrm{c}} - \boldsymbol{\mu}(\boldsymbol{q},\dot{\boldsymbol{q}})\big]\,,$$

revealing that the contact force is a constraint force which instantaneously depends on the applied input wrench $\boldsymbol{h}_{\mathrm{c}}$.

An inverse-dynamics inner control loop can be designed by choosing the control wrench $\boldsymbol{h}_{\mathrm{c}}$ as

$$\boldsymbol{h}_{\mathrm{c}} = \boldsymbol{\Lambda}(\boldsymbol{q})\mathbf{S}_{\mathrm{v}}\boldsymbol{\alpha}_{\mathrm{v}} + \mathbf{S}_{\mathrm{f}}\boldsymbol{f}_{\lambda} + \boldsymbol{\mu}(\boldsymbol{q},\dot{\boldsymbol{q}})\,,$$

where $\boldsymbol{\alpha}_v$ and $\boldsymbol{f}_\lambda$ are properly designed control inputs, which leads to the equations

$$\dot{\boldsymbol{v}} = \boldsymbol{\alpha}_v, \quad \boldsymbol{\lambda} = \boldsymbol{f}_\lambda \ ,$$

showing a complete decoupling between motion control and force control.

Then, the desired force $\boldsymbol{\lambda}_d(t)$ can be achieved by setting

$$\boldsymbol{f}_\lambda = \boldsymbol{\lambda}_d(t) \ ,$$

but this choice is very sensitive to disturbance forces, since it contains no force feedback. Alternative choices are

$$\boldsymbol{f}_\lambda = \boldsymbol{\lambda}_d(t) + \mathbf{K}_{P\lambda}\big[\boldsymbol{\lambda}_d(t) - \boldsymbol{\lambda}(t)\big] \ ,$$

or

$$\boldsymbol{f}_\lambda = \boldsymbol{\lambda}_d(t) + \mathbf{K}_{I\lambda} \int_0^t \big[\boldsymbol{\lambda}_d(\tau) - \boldsymbol{\lambda}(\tau)\big]\mathrm{d}\tau \ ,$$

where $\mathbf{K}_{P\lambda}$ and $\mathbf{K}_{I\lambda}$ are suitable positive-definite matrix gains. The proportional feedback is able to reduce the force error due to disturbance forces, while the integral action is able to compensate for constant bias disturbances.

Velocity control is achieved by setting

$$\boldsymbol{\alpha}_v = \dot{\boldsymbol{v}}_d(t) + \mathbf{K}_{Pv}\big[\boldsymbol{v}_d(t) - \boldsymbol{v}(t)\big]$$
$$+ \mathbf{K}_{Iv} \int_0^t \big[\boldsymbol{v}_d(\tau) - \boldsymbol{v}(\tau)\big]\mathrm{d}\tau \ ,$$

where $\mathbf{K}_{Pv}$ and $\mathbf{K}_{Iv}$ are suitable matrix gains. It is straightforward to show that asymptotic tracking of $\boldsymbol{v}_d(t)$ and $\dot{\boldsymbol{v}}_d(t)$ is ensured with exponential convergence for any choice of positive-definite matrices $\mathbf{K}_{Pv}$ and $\mathbf{K}_{Iv}$.

Notice that the implementation of force feedback requires the computation of vector $\boldsymbol{\lambda}$ from the measurement of the end-effector wrench $\boldsymbol{h}_e$ as $\mathbf{S}_f^\dagger \mathbf{v}_e$, being $\mathbf{S}_f^\dagger$ a suitable pseudoinverse of matrix $\mathbf{S}_f$. Analogously, vector $\boldsymbol{v}$ can be computed from $\mathbf{v}_e$ as $\mathbf{S}_v^\dagger \mathbf{v}_e$.

The hypothesis of rigid contact can be removed, and this implies that along some directions both motion and force are allowed, although they are not independent. Hybrid force/motion control schemes can be defined also in this case Villani and De Schutter (2008).

Summary and Future Directions

This entry has sketched the main approaches to force control in a unifying perspective. However, there are many aspects that have not been considered here. The two major paradigms of force control (impedance and hybrid force/motion control) are based on several simplifying assumptions that are only partially satisfied in practical implementations and that have been partially removed in more advanced control methods.

Notice that the performance of a force-controlled robotic system depends on the interaction with a changing environment which is very difficult to model and identify correctly. Hence, the standard performance indices used to evaluate a control system, i.e., stability, bandwidth, accuracy, and robustness, cannot be defined by considering the robotic system alone, as for the case of robot motion control, but must be always referred to the particular contact situation at hand.

Force control in industrial applications can be considered as a mature technology, although, for the reason explained above, standard design methodologies are not yet available. Force control techniques are employed also in medical robotics, haptic systems, telerobotics, humanoid robotics, micro-robotics, and nano robotics. An interesting field of application is related to human-centered robotics, where control plays a key role to achieve adaptability, reaction capability, and safety. Robots and biomechatronic systems based on the novel variable impedance actuators, with physically adjustable compliance and damping, capable to react softly when touching the environment, necessitate the design of specific control laws. The combined use of exteroceptive sensing (visual, depth, proximity, force, tactile sensing) for reactive control in the presence of uncertainty represents another challenging research direction.

Frequency Domain System Identification

Johan Schoukens and Rik Pintelon
Department ELEC, Vrije Universiteit Brussel, Brussels, Belgium

Abstract

In this chapter we give an introduction to frequency domain system identification. We start from the identification work loop in ► System Identification: An Overview, Fig. 4, and we discuss the impact of selecting the time or frequency domain approach on each of the choices that are in this loop. Although there is a full theoretical equivalence between the time and frequency domain identification approach, it turns out that, from practical point of view, there can be a natural preference for one of both domains.

Keywords

Discrete and continuous time models; Experiment setup; Frequency and time domain identification; Plant and noise model

Introduction

System identification provides methods to build a mathematical model for a dynamical system starting from measured input and output signals (▶ System Identification: An Overview; see the section "Models and System Identification"). Initially, the field was completely dominated by the time domain approach, and the frequency domain was used to interpret the results (Ljung and Glover 1981). This picture changed in the nineteenth of the last century by the development of advanced frequency domain methods (Ljung 2006; Pintelon and Schoukens 2012), and nowadays it is widely accepted that there is a full theoretical equivalence between time and frequency domain system identification under some weak conditions (Agüero et al. 2009; Pintelon and Schoukens 2012). Dedicated toolboxes are available for both domains (Kollar 1994; Ljung 1988). This raises the question how to choose between time and frequency domain identification. Many times the choice between both approaches can be made based on the user's familiarity with one of two methods. However, for some problems it turns out that there is a natural preference for the time or the frequency domain. This contribution discusses the main issues that need to be considered when making this choice, and it provides additional insights to guide the reader to the best solutions for her/his problem.

In the identification work loop ▶ System Identification: An Overview, Fig. 4, we need to address three important questions (Ljung 1999, Sect. 1.4; Söderström and Stoica 1989, Chap. 1; Pintelon and Schoukens 2012, Sect. 1.4) that directly interact with the choice between time and frequency domain system identification:

- What data are available? What data are needed? This discussion will influence the selection of the measurement setup, the model choice, and the design of the experiment.
- What kind of models will be used? We will mainly focus on the identification of discrete time and continuous time models, using exactly the same frequency domain tools.

- How will the model be matched to the data? This question boils down to the choice of a cost function that measures the distance between the data and the model. We will discuss the use of nonparametric weighting functions in the frequency domain.

In the next sections, we will address these and similar questions in more detail. First, we discuss the measurement of the raw data. The choices that are made in this step will have a strong impact on many user aspects of the identification process. The frequency domain formulation will turn out to be a natural choice to propose a unified formulation of the system identification problem, including discrete and continuous time modeling. Next, a generalized frequency domain description of the system relation will be proposed. This model will be matched to the data, using a weighted least squares cost function, formulated in the frequency domain identification. This will allow for the use of nonparametric weighting functions, based on a nonparametric preprocessing of the data. Eventually, some remaining user aspects are discussed.

Data Collection

In this section, we discuss the measurement assumptions that are made when the raw data are collected. It will turn out that these will directly influence the natural choice of the models that are used to describe the continuous time physical systems.

### Time Domain and Frequency Domain Measurements

The data can be collected either in the time or in the frequency domain, and we discuss briefly both options.

Time Domain Measurements

Most measurements are nowadays made in the time domain because very fast high-quality analog-to-digital convertors (ADC) became available at a low price. These allow us to sample

Frequency Domain System Identification, Fig. 1 Comparison of the ZOH and BL signal reconstruction of a discrete time sequence: (**a**) time domain: $\cdots$ BL, – ZOH; (**b**) spectrum ZOH signal; (**c**) spectrum BL signal
and discretize the continuous time input and output signals and process these on a digital computer. Also the excitation signals are mostly generated from a discrete time sequence with a digital-to-analog convertor (DAC).

The continuous time input and output signals $u_c(t), y_c(t)$ of the system to be modeled are measured at the sampling moments $t_k = kT_s$, with $T_s = 1/f_s$ the sampling period and f_s the sampling frequency: $u(k) = u_c(kT_s)$, and $y(k) = y_c(kT_s)$. The discrete time signals $u(k), y(k), k = 1, \cdots, N$ are transformed to the frequency domain using the discrete Fourier transform (DFT) (▶ Nonparametric Techniques in System Identification, Eq. 1), resulting in the DFT spectra $U(l), Y(l)$, at the frequencies $f_l = l\frac{f_s}{N}$. Making some abuse of notation, we will reuse the same symbols later in this text, to denote the Z-transform of the signals, for example, $Y(z)$ will also be used for the Z-transform of $y(k)$.

Frequency Domain Measurements

A major exception to this general trend toward time domain measurements are the (high-frequency) network analyzers that measure the transfer function of a system frequency by frequency, starting from the steady-state response to a sine excitation. The frequency is stepped over the frequency

band of interest, resulting directly in a measured frequency response function at a user selected set of frequencies $\omega_k, k = 1, \cdots, F$:

$$G(\omega_k).$$

From the identification point of view, we can easily fit the latter situation in the frequency domain identification framework, by putting

$$U(k) = 1, Y(k) = G(\omega_k).$$

For that reason we will focus completely on the time domain measurement approach in the remaining part of this contribution.

Zero-Order-Hold and Band-Limited Setup: Impact on the Model Choice

No information is available on how the continuous time signals $u_c(t), y_c(t)$ vary in between the measured samples $u(k), y(k)$. For that reason we need to make an assumption and make sure that the measurement setup is selected such that the intersample assumption is met. Two intersample assumptions are very popular (Pintelon and Schoukens 2012; Schoukens et al. 1994, pp. 498–512): the zero-order-hold (ZOH) and the band-limited assumption (BL). Both options are shown in Fig. 1 and discussed below. The choice

of these assumptions does not only affect the measurement setup; it has also a strong impact on the selection between a continuous or a discrete time model choice.

Zero-Order Hold

The ZOH setup assumes that the excitation remains constant in between the samples. In practice, the model is identified between the discrete time reference signal in the memory of the generator and the sampled output. The intersample behavior is an intrinsic part of the model: if the intersample behavior changes, also the corresponding model will change. The ZOH assumption is very popular in digital control. In that case the sampling frequency f_s is commonly chosen 10 times larger than the frequency band of interest.

A discrete time model gives, in case of noise-free data, an exact description between the sampled input $u(k)$ and output $y(k)$ of the continuous time system:

$$y(k) = G(q, \theta)u(k)$$

in the time domain (▶ System Identification: An Overview, Eq. 6). In this expression, q denotes the shift operator (time domain), and it is replaced by z in the z-domain description (transfer function description):

$$Y(z) = G(z, \theta)U(z).$$

Evaluating the transfer function at the unit circle by replacing $z = e^{i\omega}$ results in the frequency domain description of the system:

$$Y(e^{i\omega}) = G(e^{i\omega}, \theta)U(e^{i\omega})$$

(▶ System Identification: An Overview, Eq. 34).

Band-Limited Setup

The BL setup assumes that above a given frequency $f_{max} < f_s/2$, there is no power in the signals. The continuous time signals are filtered by well-tuned anti-alias filters (cutoff frequency $f_{max} < f_s/2$), before they are sampled. Outside the digital control world, the BL setup is the standard choice for discrete time measurements. Without using anti-alias filters, large errors can be created due to aliasing effects: the high frequency ($f > f_s/2$) content of the measured signals is folded down in the frequency band of interest and act there as a disturbance. For that reason it is strongly advised to use always anti-alias filters in the measurement setup.

The exact relation between BL signals is described by a continuous time model, for example, in the frequency domain:

$$Y(\omega) = G(\omega, \theta)U(\omega)$$

(Schoukens et al. 1994).

Combining Discrete Time Models and BL Data

It is also possible to identify a discrete time model between the BL data, at a cost of creating (very) small model errors (Schoukens et al. 1994). This is the standard setup that is used in digital signal procession applications like digital audio processing. The level of the model errors can be reduced by lowering the ratio f_{max}/f_s or by increasing the model order. In a properly designed setup, the discrete time model errors can be made very small, e.g., relative errors below 10^{-5}. In Table 1 an overview of the models corresponding to the experimental conditions is given.

Extracting Continuous Time Models from ZOH Data

Although the most robust and practical choice to identify a continuous time model is to start from BL data, it is also possible to extract a continuous time model under the ZOH setup. A first possibility is to assume that the ZOH assumption is perfectly met, which is a very hard assumption to realize in practice. In that case the continuous time model can be retrieved by a linear step invariant transformation of the discrete time model. A second possibility is to select a very high sample frequency with respect to the bandwidth of the system. In that case it is advantageous to describe the discrete time model using the delta operator (Goodwin 2010), and

Frequency Domain System Identification, Table 1 Relations between the continuous time system $G(s)$ and the identified models as a function of the signal and model choices

	DT-model (Assuming ZOH-setup)	CT-model (Assuming BL-setup)
ZOH setup	Exact DT-model $$G(z) = \left(1 - z^{-1}\right) Z \left\{\frac{G(s)}{S}\right\}$$ **'standard conditions DT modelling'**	Not studied
BL setup	Approximate DT model $$\tilde{G}(z)\, \tilde{G}\left(z = e^{j\omega T_s}\right) \approx G(s = j\omega),\ |\omega| < \frac{\omega_s}{2}$$ **'digital signal processing field'**	Exact CT-model $G(s)$ **'standard conditions CT modelling'**

we have that the coefficients of the discrete time model converge to those of the continuous time model.

Models of Cascaded Systems

In some problems we want to build models for a cascade of two systems G_1, G_2. It is well known that the overall transfer function G is given by the product $G(\omega) = G_1(\omega)G_2(\omega)$. This result holds also for models that are identified under the BL signal assumption: the model for the cascade will be the product of the models of the individual systems. However, the result does not hold under the ZOH assumption, because the intermediate signal between G_1, G_2 does not meet the ZOH assumption. For that reason, the ZOH model of a cascaded system is not obtained by cascading the ZOH models of the individual systems.

Experiment Design: Periodic or Random Excitations?

In general, arbitrary data can be used to identify a system as long as some basic requirements are respected (▶ System Identification: An Overview, section on Experiment Design). Imposing periodic excitations can be an important restriction of the user's freedom to design the experiment, but we will show in the next sections that it offers also major advantages at many steps in the identification work loop (▶ System Identification: An Overview, Fig. 4).

With the availability of arbitrary wave form generators, it became possible to generate arbitrary periodic signals. The user should make two major choices during the design of the periodic excitation: the selection of the amplitude spectrum (How is the available power distributed over the frequency?) and the choice of the frequency resolution (What is the frequency step between two successive points of the measured FRF?) (Pintelon and Schoukens 2012, Sect. 5.3).

The amplitude spectrum is mainly set by the requirement that the excited frequency band should cover the frequency band of interest. A white noise excitation covers the full frequency band, including those bands that are of no interest for the user. This is a waste of power and it should be avoided. Designing a good power spectrum for identification and control purposes is discussed in ▶ Experiment Design and Identification for Control.

The frequency resolution $f_0 = 1/T$ is set by the inverse of the period of the signal. It should be small enough so that no important dynamics are missed, e.g., a very sharp mechanical resonance.

The reader should be aware that exactly the same choices have to be made during the design of nonperiodic excitations. If, for example, a random noise excitation is used, the frequency resolution is also restricted by the length of the experiment T_m and the corresponding frequency resolution is again $f_0 = 1/T_m$. The power spectrum of the noise excitation should be well shaped using a digital filter.

Nonparametric Preprocessing of the Data in the Frequency Domain

Before a parametric model is identified from the raw data, a lot of information can be gained, almost for free, by making a nonparametric analysis of the data. This can be done with very

little user interaction. Some of these methods are explicitly linked to the periodic nature of the data, other methods apply also to random excitations.

Nonparametric Frequency Analysis of Periodic Data

By using simple DFT techniques, the following frequency domain information is extracted from sampled time domain data $u(t), y(t), t = 1, \ldots, N$ (Pintelon and Schoukens 2012):

- The signal information: $U(l), Y(l)$, the DFT spectra of the input and output, evaluated at the frequencies $l f_0$, with $k = 1, 2, \cdots, F$.
- Disturbing noise variance information: The full data record is split, so that each subrecord contains a single period. For each of these, the DFT spectrum is calculated. Since the signals are periodic, they do not vary from one period to the other, so that the observed variations can be attributed to the noise. By calculating the sample mean and variance over the periods at each frequency, a nonparametric noise analysis is available. The estimated variances $\hat{\sigma}_U^2(k), \hat{\sigma}_Y^2(k)$ measure the disturbing noise power spectrum at frequency f_k on the input and the output respectively. The covariance $\hat{\sigma}_{YU}^2(k)$ characterizes the linear relations between the noise on the input and the output.

This is very valuable information because, even before starting the parametric identification step, we get already full access to the quality of the raw data. As a consequence, there is also no interference between the plant model estimation and the noise analysis: plant model errors do not affect the estimated noise model. It is also important to realize that there is no user interaction requested to make this analysis and it follows directly from a simple DFT analysis of the raw data. These are two major advantages of using periodic excitations.

Nonlinear Analysis

Using well-designed periodic excitations, it is possible to detect the presence of nonlinear distortions during the nonparametric frequency step. The level of the nonlinear distortions at the output

of the system is measured as a function of the frequency, and it is even possible to differentiate between even (e.g., x^2) and odd (e.g., x^3) distortions. While the first only act as disturbing noise in a linear modeling framework, the latter will also affect the linearized dynamics and can change, for example, the pole positions of a system (Pintelon and Schoukens 2012, Sect. 4.3).

Noise and Data Reduction

By averaging the periodic signals over the successive periods, we get a first reduction of the noise. An additional noise reduction is possible when not all frequencies are excited. If a very wide frequency band has to be covered, a fine frequency resolution is needed at the low frequencies, whereas in the higher frequency bands, the resolution can be reduced. Signals with a logarithmic frequency distribution are used for that purpose. Eliminating the unexcited frequencies does not only reduce the noise, it also reduces significantly the amount of raw data to be processed. By combining different experiments that cover each a specific frequency band, it is possible to measure a system over multiple decades, e.g., electrical machines are measured from a few mHz to a few kHz.

In a similar way, it is also possible to focus the fit on the frequency band of interest by including only those frequencies in the parametric modeling step.

High-Quality Frequency Response Function Measurements

For periodic excitations, it is very simple to obtain high-quality measurements of the nonparametric frequency response function of the system. These results can be extended to random excitations at a cost of using more advanced algorithms that require more computation time (Pintelon and Schoukens, Chap. 7). This approach is discussed in detail in ▶ Nonparametric Techniques in System Identification (Eq. 1).

Generalized Frequency Domain Models

A very important step in the identification work loop is the choice of the model class (▶ System Identification: An Overview, Fig. 4). Although most physical systems are continuous time, the models that we need might be either discrete time (e.g., digital control, computer simulations, digital signal processing) or continuous time (e.g., physical interpretation of the model, analog control) (Ljung 1999, Sects. 2.1 and 4.3). A major advantage of the frequency domain is that both model classes are described by the same transfer function model. The only difference is the choice of the frequency variable. For continuous time models we operate in the Laplace domain, and the frequency variable is retrieved on the imaginary axis by putting $s = j\omega$. For discrete time systems we work on the unit circle that is described by the frequency variable $z = e^{j 2\pi f/f_s}$. The application class can be even extended to include diffusion phenomena by putting $\Omega = \sqrt{j\omega}$ (Pintelon et al. 2005). From now on we will use the generalized frequency variable Ω, and depending on the selected domain, the proper substitution $j\omega$, $e^{j 2\pi f/f_s}$, $\sqrt{j\omega}$ should be made. The unified discrete and continuous time description

$$Y(k) = G(\Omega_k, \theta)U(k).$$

illustrates also very nicely that in the frequency domain there is a strong similarity between discrete and continuous time system identification.

To apply this model to finite length measurements, it should be generalized to include the effect of the initial conditions (time domain) or the begin and end effects (called leakage in the frequency domain). See ▶ Nonparametric Techniques in System Identification, "The Leakage Problem" section. The amazing result is that in the frequency domain, both effects are described by exactly the same mathematical expression. This leads eventually to the following model in the frequency domain that is valid for periodic and arbitrary (nonperiodic) BL or ZOH excitations (Pintelon et al. 1997; McKelvey 2002; Pintelon and Schoukens 2012, Chap. 6):

$$Y(k) = G(\Omega, \theta)U(k) + T_G(\Omega, \theta)$$

which becomes for SISO (single-input-single-output) systems:

$$G(\Omega, \theta) = \frac{B(\Omega, \theta)}{A(\Omega, \theta)}, \text{ and } T_G(\Omega, \theta) = \frac{I(\Omega, \theta)}{A(\Omega, \theta)}.$$

A, B, I are all polynomials in Ω. The transient term $T_G(\Omega, \theta)$ models transient and leakage effects. It is most important for the reader to realize that this is an exact description for noise free data. Observe that it is very similar to the description in the time domain: $y(t) = G(q, \theta)u(t) + t_G(t, \theta)$. In that case the transient term $t_G(t, \theta)$ models the initial transient that is due to the initial conditions.

Parametric Identification

Once we have the data and the model available in the frequency domain, we define the following weighted least squares cost function to match the model to the data (Schoukens et al. 1997):

$$V(\theta) = \frac{1}{F} \sum_{k=1}^{F} \frac{\left| \hat{Y}(k) - G(\Omega_k, \theta) \hat{U}(k) - T_G(\Omega_k, \theta) \right|^2}{\hat{\sigma}_Y^2(k) + \hat{\sigma}_U^2(k) |G(\Omega_k, \theta)|^2 - 2\mathrm{Re}(\hat{\sigma}_{YU}^2(k) G(\Omega_k, \theta))}.$$

The properties of this estimator are fully studied in Schoukens et al. (1999) and Pintelon and Schoukens (2012, Sect. 10.3), and it is shown that it is a consistent and almost efficient estimator under very mild conditions.

The formal link with the time domain cost function, as presented in ▶ System Identification: An Overview, can be made by assuming that the input is exactly known ($\hat{\sigma}_U^2(k) = 0$, $\hat{\sigma}_{YU}^2(k) = 0$), and replacing the nonparametric

noise model on the output by a parametric model:

$$\hat{\sigma}_Y^2(k) = \lambda \left| H(\Omega_k, \theta) \right|^2.$$

These changes reduce the cost function, within a parameter independent constant λ to

$$V_F(\theta) = \frac{1}{F} \sum_{k=1}^{F} \frac{\left| \hat{Y}(k) - G(\Omega_k, \theta) U_0(k) - T_G(\Omega_k, \theta) \right|^2}{\left| H(\Omega_k, \theta) \right|^2},$$

which is exactly the same expression as Eq. 37 in ▶ System Identification: An Overview, provided that the frequencies Ω_k cover the full unit circle and the transient term T_G is omitted. The latter models the initial condition effects in the time domain. The expression shows the full equivalence with the classical discrete time domain formulation. If only a subsection of the full unit circle is used for the fit, the additional term $N \log \det \Lambda$ in ▶ System Identification: An Overview, Eq. 21 should be added to the cost function $V_F(\theta)$.

Additional User Aspects in Parametric Frequency Domain System Identification

In this section we highlight some additional user aspects that are affected by the choice for a time or frequency approach to system identification.

Nonparametric Noise Models

The use of a nonparametric noise model is a natural choice in the frequency domain. It is of course also possible to use the parametric noise model in the frequency domain formulation, but then we would lose two major advantages of the frequency domain formulation: (i) For periodic excitations, there is no interaction between the identification of the plant model and the nonparametric noise model. Plant model errors do not show up in the noise model. (ii) The availability of the nonparametric noise models eliminates the need for tuning the parametric noise model order, resulting in algorithms that are easier to use.

A disadvantage of using a nonparametric noise model is that we can no longer express that the noise model can share some dynamics with the plant model, for example, when the disturbance is an unobserved plant input.

It is also possible to use a nonparametric noise model in the time domain. This leads to a Toeplitz weighting matrix, and the fast numerical algorithms that are used to deal with these make use internally of FFT (fast Fourier transform) algorithms which brings us back to the frequency domain representation of the data.

Stable and Unstable Plant Models

In the frequency domain formulation, there is no special precaution needed to deal with unstable models, so that we can tolerate these models without any problem. There are multiple reasons why this can be advantageous. The most obvious one is the identification of an unstable system, operating in a stabilizing closed loop. It can also happen that the intermediate models that are obtained during the optimization process are unstable. Imposing stability at each iteration can be too restrictive, resulting in estimates that are trapped in a local minimum. A last significant advantage is the possibility to split the identification problem (extract a model from the noisy data) and the approximation problem (approximate the unstable model by a stable one). This allows us to use in each step a cost function that is optimal for that step: maximum noise reduction in the first step, followed by a user-defined approximation criterion in the second step.

Model Selection and Validation

An important step in the system identification procedure is the tuning of the model complexity, followed by the evaluation of the model quality on a fresh data set. The availability of a

nonparametric noise model and a high-quality frequency response function measurement simplifies these steps significantly:

Absolute Interpretation of the Cost Function: Impact on Model Selection and Validation

The weighted least squares cost function, using the nonparametric noise weighting, is a normalized function. Its expected value equals $E\{V(\hat{\theta})\} = (F - n_\theta/2)/F$, with n_θ the number of free parameters in the model and F the number of frequency points. A cost function that is far too large points to remaining model errors. Unmodeled dynamics result in correlated residuals (difference between the measured and the modeled FRF): the user should increase the model order to capture these dynamics in the linear model. A cost function that is far too large, while the residuals are white, points to the presence of nonlinear distortions: the best linear approximation is identified, but the user should be aware that this approximation is conditioned on the actual excitation signal. A cost function that is far too low points to an error in the preprocessing of the data, resulting in a bad noise model.

Missing Resonances

Some systems are lightly damped, resulting in a resonant behavior, for example, a vibrating mechanical structure. By comparing the parametric transfer function model with the nonparametric FRF measurements, it becomes clearly visible if a resonance is missed in the model. This can be either due to a too simple model structure (the model order should be increased), or it can appear because the model is trapped in a local minimum. In the latter case, better numerical optimization and initialization procedures should be looked for.

Identification in the Presence of Noise on the Input and Output Measurements

Within the band-limited measurement setup, both the input and the output have to be measured. This leads in general to an identification framework where both the input and the output are disturbed by noise. Such problems are studied in the errors-in-variables (EIV)

framework (Soderstrom 2012). A special case is the identification of a system that is captured in a feedback loop. In that case we have that the noisy output measurements are fed back to the input of the system which creates a dependency between the input and output disturbance. We discuss both situations briefly below.

Errors-in-Variables Framework

The major difficulty of the EIV framework is the simultaneous identification of the plant model describing the input-output relations, the noise models that describe the input and the output noise disturbances, and the signal model describing the coloring of the excitation (Soderstrom 2012). Advanced identification methods are developed, but today it is still necessary to impose strong restrictions on the noise models, e.g., correlations between input and output noise disturbances are not allowed. The periodic frequency domain approach encapsulates the general EIV, including mutually correlated colored input–output noise. Again, a full nonparametric noise model is obtained in the preprocessing step. This reduces the complexity of the EIV problem to that of a classical weighted least squares identification problem which makes a huge difference in practice (Pintelon and Schoukens 2012; Söderström et al. 2010).

Identification in a Feedback Loop

Identification under feedback conditions can be solved in the time domain prediction error method (Ljung 1999, Sect. 13.4; Söderström and Stoica 1989, Chap. 10). This leads to consistent estimates, provided that the exact plant and noise model structure and order is retrieved. In the periodic frequency domain approach, a nonparametric noise model is extracted (variances input and output noise, and covariance between input and output noise) in the preprocessing step, without any user interaction. Next, these are used as a weighting in the weighted least squares cost function which leads to consistent estimates provided that the plant model is flexible enough to capture the true plant

transfer function (Pintelon and Schoukens 2012, Sect. 9.18).

Summary and Future Directions

Theoretically, there is a full equivalence between the time and frequency domain formulation of the system identification problem. In many practical situations the user can make a free choice between both approaches, based on nontechnical arguments like familiarity with one of both domains. However, some problems can be easier formulated in the frequency domain. Identification of continuous time models is not more involved than retrieving a discrete time model. The frequency domain formulation is also the natural choice to use nonparametric noise models. This eliminates the request to select a specific noise model structure and order, although this might be a drawback for experienced users who can take advantage of a clever choice of this structure. The advantages that are directly linked to periodic excitation signals can be explored most naturally in the frequency domain: the noise model is available for free, EIV identification is not more involved than the output error identification problem, and identification under feedback conditions does not differ from open-loop identification. Nonstationary effects are an example of a problem that will be easier detected in the time domain. In general, we advise the reader to take the best of both approaches and to swap from one domain to the other whenever it gives some advantage to do so. In the future, it will be necessary to extend the framework to include a characterization of nonlinear and time-varying effects.

Frequency-Response and Frequency-Domain Models

Abbas Emami-Naeini and J. David Powell
Stanford University, Stanford, CA, USA

Abstract

A major advantage of using frequency response is the ease with which experimental information can be used for design purposes. Raw measurements of the output amplitude and phase of a plant undergoing a sinusoidal input excitation are sufficient to design a suitable feedback control. No intermediate processing of the data (such as finding poles and zeros or determining system matrices) is required to arrive at the system model. The wide availability of computers has rendered this advantage less important now than it was years ago; however, for relatively simple systems, frequency response is often still the most cost-effective design method. The method is most effective for systems that are stable in open-loop. Yet another advantage is that it is the easiest method to use for designing dynamic compensation.

Keywords

Introduction: Frequency Response

A very common way to use the exponential response of linear time-invariant systems (LTIs) is in finding the **frequency response,** or response to a sinusoid. First we express the sinusoid as a sum of two exponential expressions (Euler's relation):

$$A\cos(\omega t) = \frac{A}{2}(e^{j\omega t} + e^{-j\omega t}). \qquad (1)$$

Suppose we have an LTI system with input u and output y. If we let $s = j\omega$ in the transfer function $G(s)$, then the response to $u(t) = e^{j\omega t}$ is $y(t) = G(j\omega)e^{j\omega t}$; similarly, the response to $u(t) = e^{-j\omega t}$ is $G(-j\omega)e^{-j\omega t}$. By superposition, the response to the sum of these two exponentials, which make up the cosine signal, is the sum of the responses:

$$y(t) = \frac{A}{2}[G(j\omega)e^{j\omega t} + G(-j\omega)e^{-j\omega t}]. \quad (2)$$

The transfer function $G(j\omega)$ is a complex number that can be represented in polar form or in magnitude-and-phase form as $G(j\omega) = M(\omega)e^{j\phi(\omega)}$, or simply $G = Me^{j\phi}$. With this substitution, Eq. (2) becomes for a specific input frequency $\omega = \omega_o$

$$y(t) = \frac{A}{2}M\left(e^{j(\omega t + \varphi)} + e^{-j(\omega t + \varphi)}\right),$$

$$= AM\cos(\omega t + \varphi), \qquad (3)$$

$$M = |G(j\omega)| = |G(s)|_{s=j\omega_o}$$

$$= \sqrt{\{\text{Re}[G(j\omega_o)]\}^2 + \{\text{Im}[G(j\omega_o)]\}^2},$$

$$\varphi = \angle G(j\omega) = \tan^{-1}\left[\frac{\text{Im}[G(j\omega_o)]}{\text{Re}[G(j\omega_o)]}\right]. \quad (4)$$

This means that if an LTI system represented by the transfer function $G(s)$ has a sinusoidal input with magnitude A, the output will be sinusoidal at the *same* frequency with magnitude AM and will be shifted in phase by the angle φ. M is usually referred to as the **amplitude ratio** or **magnitude** and φ is referred to as the **phase** and they are both functions of the input frequency, ω. The frequency response can be measured experimentally quite easily in the laboratory by driving the system with a known sinusoidal input, letting the transient response die, and measuring the steady-state amplitude and phase of the system's output as shown in Fig. 1. The input frequency is set to sufficiently many values so that curves such as the one in Fig. 2 are obtained. Bode suggested that we plot $\log|M|$ vs. $\log\omega$ and $\varphi(\omega)$ vs. $\log\omega$ to best show the essential features of $G(j\omega)$. Hence, such plots are referred to as Bode plots. Bode plotting techniques are discussed in Franklin et al. (2015).

We are interested in analyzing the frequency response not only because it will help us understand how a system responds to a sinusoidal input, but also because evaluating $G(s)$ with s taking on values along the $j\omega$ axis will prove to be very useful in determining the stability of a closed-loop system. Since the $j\omega$ axis is the boundary between stability and instability; evaluating $G(j\omega)$ provides information that allows us to determine closed-loop stability from the open-loop $G(s)$.

For the second-order system

$$G(s) = \frac{1}{(s/\omega_n)^2 + 2\zeta(s/\omega_n) + 1}, \quad (5)$$

the Bode plot is shown in Fig. 3 for various values of ζ.

A natural specification for system performance in terms of frequency response is the **bandwidth**, defined to be the maximum frequency at which the output of a system will track an input sinusoid in a satisfactory manner. By convention, for the system shown in Fig. 4 with a sinusoidal input r, the bandwidth is the frequency of r at which the output y is attenuated to a factor of 0.707 times the input (If the output is a voltage across a 1-Ω resistor, the power is v^2 and when $|v| = 0.707$, the power is reduced by a factor of 2. By convention, this is called the half-power point.). Figure 5 depicts the idea graphically for the frequency response of the *closed-loop* transfer function
$$\frac{Y(s)}{R(s)} \triangleq \mathcal{T}(s) = \frac{KG(s)}{1 + KG(s)}. \quad (6)$$

Frequency-Response and Frequency-Domain Models, Fig. 1 Response of $G(s) = \frac{1}{(s+1)}$ to the input $u = \sin 10t$ (Source: Franklin et al. (2010), p. 298, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

The plot is typical of most closed-loop systems in that (1) the output follows the input ($|\mathcal{T}| \cong 1$) at the lower excitation frequencies and (2) the output ceases to follow the input ($|\mathcal{T}| < 1$) at the higher excitation frequencies. The maximum value of the frequency-response magnitude is referred to as the **resonant peak M_r**.

Bandwidth is a measure of speed of response and is therefore similar to time-domain measures such as rise time and peak time or the s-plane measure of dominant-root(s) natural frequency. In fact, if the $KG(s)$ in Fig. 4 is such that the closed-loop response is given by Fig. 3a, we can see that the bandwidth will equal the natural frequency of the closed-loop root (that is, $\omega_{BW} = \omega_n$ for a closed-loop damping ratio of $\zeta = 0.7$). For other damping ratios, the bandwidth is approximately equal to the natural frequency of the closed-loop roots, with an error typically less than a factor of 2.

For a second-order system, the time responses are functions of the pole-location parameters ζ and ω_n. If we consider the curve for $\zeta = 0.5$ to

be an average, the rise time (Rise time t_r.) from $y = 0.1$ to $y = 0.9$ is approximately $\omega_n t_r = 1.8$. Thus, we can say that

$$t_r \cong \frac{1.8}{\omega_n}. \tag{7}$$

Although this relationship could be embellished by including the effect of the damping ratio, it is important to keep in mind how Eq. (7) is typically used. It is accurate only for a second-order system with no zeros; for all other systems it is a rough approximation to the relationship between t_r and ω_n. Most systems being analyzed for control systems design are more complicated than the pure second-order system, so designers use Eq. (7) with the knowledge that it is a rough approximation only. Hence, for a second-order system the bandwidth is inversely proportional to the rise time, t_r. Hence we are able to link the time and frequency domain quantities in this way.

The definition of the bandwidth stated here is meaningful for systems that have a low-pass filter behavior, as is the case for any physical control

Frequency-Response and Frequency-Domain Models, Fig. 3 Frequency responses of standard second-order systems (**a**) magnitude (**b**) phase (Source: Franklin et al. (2010), p. 303, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)
system. In other applications the bandwidth may be defined differently. Also, if the ideal model of the system does not have a high-frequency roll-off (e.g., if it has an equal number of poles and zeros), the bandwidth is infinite; however, this does not occur in nature as nothing responds well at infinite frequencies.
In many cases, the designer's primary concern is the error in the system due to disturbances rather than the ability to track an input. For error

analysis, we are more interested in the sensitivity function $\mathcal{S}(s) = 1 - \mathcal{T}(s)$, rather than $\mathcal{T}(s)$. For most open-loop systems with high gain at low frequencies, $\mathcal{S}(s)$ for a disturbance input has very low values at low frequencies and grows as the frequency of the input or disturbance approaches the bandwidth. For analysis of either $\mathcal{T}(s)$ or $\mathcal{S}(s)$, it is typical to plot their response versus the frequency of the input. Either frequency response for control systems design can be evaluated using

the computer or can be quickly sketched for simple systems using the efficient methods described in Franklin et al. (2015). The methods described next are also useful to expedite the

design process as well as to perform sanity checks on the computer output.

Neutral Stability: Gain and Phase Margins

In the early days of electronic communications, most instruments were judged in terms of their frequency response. It is therefore natural that when the feedback amplifier was introduced, techniques to determine stability in the presence of feedback were based on this response.

Suppose the closed-loop transfer function of a system is known. We can determine the stability of a system by simply inspecting the

Frequency-Response and Frequency-Domain Models, Fig. 4 Unity feedback system (Source: Franklin et al. (2010), p. 304, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

Frequency-Response and Frequency-Domain Models, Fig. 5 Definitions of bandwidth and resonant peak (Source: Franklin et al. (2010), p. 304, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

Frequency-Response and Frequency-Domain Models, Fig. 6 Stability example: (**a**) system definition; (**b**) root locus (Source: Franklin et al. (2010), p. 318, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

denominator in factored form (because the factors give the system roots directly) to observe whether the real parts are positive or negative. However, the closed-loop transfer function is usually not known. In fact, the whole purpose behind understanding the root-locus technique is to be able to find the factors of the denominator in the closed-loop transfer function, given only the open-loop transfer function. Another way to determine closed-loop stability is to evaluate the frequency response of the *open-loop* transfer function $KG(j\omega)$ and then perform a test on that response. Note that this method also does not require factoring the denominator of the closed-loop transfer function. In this section we will explain the principles of this method. Note that this method also does not require factoring the denominator of the closed-loop transfer function. Here we will explain the principles of this method.

Suppose we have a system defined by Fig. 6a and whose root locus behaves as shown in Fig. 6b; that is, instability results if K is larger than 2. The neutrally stable points lie on the imaginary axis – that is, where $K = 2$ and $s = j\,1.0$. Furthermore, all points on the root locus have the property that

$$|KG(s)| = 1 \quad \text{and} \quad \angle G(s) = -180°.$$

At the point of neutral stability we see that these root-locus conditions hold for $s = j\omega$, so

$$|KG(j\omega)| = 1 \quad \text{and} \quad \angle G(j\omega) = -180°. \tag{8}$$

Thus, a Bode plot of a system that is neutrally stable (that is, with K defined such that a closed-loop root falls on the imaginary axis) will satisfy the conditions of Eq. (8). Figure 7 shows the frequency response for the system whose root locus is plotted in Fig. 6 for various values of K. The magnitude response corresponding to $K = 2$ passes through 1 at the same frequency ($\omega = 1$ rad/s) at which the phase passes through $-180°$, as predicted by Eq. (8).

Having determined the point of neutral stability, we turn to a key question: Does increasing the gain increase or decrease the system's stability?

We can see from the root locus in Fig. 6b that any value of K less than the value at the neutrally stable point will result in a stable system. At the frequency ω where the phase $\angle G(j\omega) = -180°$ ($\omega = 1$ rad/s), the magnitude $|KG(j\omega)| < 1.0$ for stable values of K and >1 for unstable values of K. Therefore, we have the following trial stability condition, based on the character of the open-loop frequency response:

$$|KG(j\omega)| < 1 \quad \text{at} \quad \angle G(j\omega) = -180°. \tag{9}$$

This stability criterion holds for all systems for which increasing gain leads to instability and $|KG(j\omega)|$ crosses the magnitude ($=1$) once, the most common situation. However, there are systems for which an increasing gain can lead from instability to stability; in this case, the stability condition is

$$|KG(j\omega)| > 1 \quad \text{at} \quad \angle G(j\omega) = -180°. \tag{10}$$

Based on the above ideas, we can now define the robustness metrics gain and phase margins:

Phase Margin: Suppose at ω_1, $|G(j\omega_1)| = \frac{1}{K}$. How much more *phase* could the system tolerate (as a time delay, perhaps) before reaching the stability boundary? The answer to this question follows from Eq. (8), i.e., the phase margin (PM) is defined as

$$\text{PM} = \angle G(j\omega_1) - (-180°). \tag{11}$$

**Gain Margin:** Suppose at ω_2, $\angle G(j\omega_2) = -180°$. How much more *gain* could the system tolerate (as an amplifier, perhaps) before reaching the stability boundary? The answer to this question follows from Eq. (9), i.e., the gain margin (GM) is defined as

$$\text{GM} = \frac{1}{K|G(j\omega_2)|}. \tag{12}$$

There are also rare cases when $|KG(j\omega)|$ crosses magnitude ($=1$) more than once, or where an increasing gain leads to instability. A rigorous way to resolve these situations is to use the Nyquist

Frequency-Response and Frequency-Domain Models, Fig. 7 Stability example: (**a**) system definition; (**b**) root locus (Source: Franklin et al. (2010), p. 319, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)
stability criterion as discussed in Franklin et al. (2015).
Closed-Loop Frequency Response

The closed-loop bandwidth was defined earlier in this section. The natural frequency is always within a factor of 2 of the bandwidth for a second-order system. We can help establish a more exact correspondence by making a few observations. Consider a system in which $|KG(j\omega)|$ shows the typical behavior

$$|KG(j\omega)| \gg 1 \quad \text{for} \quad \omega \ll \omega_c,$$

$$|KG(j\omega)| \ll 1 \quad \text{for} \quad \omega \gg \omega_c,$$

where ω_c is the crossover frequency. The closed-loop frequency-response magnitude is approximated by

$$|\mathcal{T}(j\omega)| = \left| \frac{KG(j\omega)}{1 + KG(j\omega)} \right| \cong \begin{cases} 1, & \omega \ll \omega_c, \\ |KG|, & \omega \gg \omega_c. \end{cases} \tag{13}$$

In the vicinity of crossover, where $|KG(j\omega)| = 1$, $|\mathcal{T}(j\omega)|$ depends heavily on the PM. A PM of 90° means that $\angle G(j\omega_c) = -90°$, and therefore $|\mathcal{T}(j\omega_c)| = 0.707$. On the other hand, PM = 45° yields $|\mathcal{T}(j\omega_c)| = 1.31$.

The exact evaluation of Eq. (13) was used to generate the curves of $|\mathcal{T}(j\omega)|$ in Fig. 8. It shows that the bandwidth for smaller values of PM is typically somewhat greater than ω_c, though usually it is less than $2\omega_c$; thus,

Frequency-Response and Frequency-Domain Models, Fig. 8 Closed-loop bandwidth with respect to PM (Source: Franklin et al. (2010), p. 347, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

$$\omega_c \leq \omega_{BW} \leq 2\omega_c. \qquad (14)$$

Another specification related to the closed-loop frequency response is the resonant-peak magnitude M_r, defined in Fig. 5. For linear systems, M_r is generally related to the damping of the system. In practice, M_r is rarely used; most designers prefer to use the PM to specify the damping of a system, because the imperfections that make systems nonlinear or cause delays usually erode the phase more significantly than the magnitude.

It is also important in the design to achieve certain error characteristics and these are often evaluated as a function of the input or disturbance frequency. In some cases, the primary function of the control system is to regulate the output to a certain constant input in the presence of disturbances. For these situations, the key item of interest for the design would be the closed-loop frequency response of the error with respect to disturbance inputs.

Summary and Future Directions

The frequency response methods are the most popular because they can deal with model uncertainty and can be measured in the laboratory. A wide range of information about the system can be displayed in a Bode plot. The dynamic compensation can be carried out directly from the Bode plot. Extension of the ideas to multivariable systems has been done via singular value plots. Extension to nonlinear systems is still the subject of current research.

Fundamental Limitation of Feedback Control

Jie Chen
City University of Hong Kong, Hong Kong,
China

Abstract

Feedback systems are designed to meet many different objectives. Yet, not all design objectives are achievable as desired due to the fact that they are often mutually conflicting and that the system properties themselves may impose design constraints and thus limitations on the performance attainable. An important step in the control design process is then to analyze what and how system characteristics may impose constraints, and accordingly, how to make tradeoffs between different objectives by judiciously navigating between the constraints. Fundamental limitation of feedback control is an area of research that addresses these constraints, limitations, and tradeoffs.

Keywords

Bode integrals; Design tradeoff; Performance limitation; Tracking and regulation limits

Introduction

Fundamental control limitations are referred to those intrinsic of feedback that can neither be overcome nor circumvent regardless how it may be designed. By this nature, the study of fundamental limitations dwells on a Hamletian question: Can or can't it be done? What can and cannot be done? To be more specific, yet still general enough, at heart here are issues concerning the benefit and cost of feedback. We ask such questions as (1) What system characteristics may impose inherent limitations regardless of controller design? (2) What inherent constraints may exist in design, what kind of tradeoffs are to be made? (3) What are the best achievable performance limits? (4) How can the constraints, limitations, and limits be quantified, in ways meaningful for control analysis and design? Needless to say, issues of this kind are very general and in fact are commonplace in science and engineering. Analogies can be made, for example, to Shannon's theorems in communications theory, the Cramer-Rao bound in statistics, and Heisenberg's uncertainty principle in quantum mechanics; they all address the fundamental limits and limitations, though for different problems and in different contexts. The search for fundamental limitations of feedback control, as such, may be considered a quest for an "ultimate truth" or the "law of feedback."

For their fundamentality and importance, inquiries into control performance limitations have persisted over time and continue to be of vital interest. It is worth emphasizing, however, that performance limitation studies are not merely driven by intellectual curiosity, but are tantamount to better and more realistic feedback systems design and hence of tangible practical value. An analysis of performance limitations can aid control design in several aspects. First, it may provide a fundamental limit on the best performance attainable irrespective of controller design, thus furnishing a guiding benchmark in the design process. Secondly, it helps a designer assess what and how system properties may be inherently conflicting and thus pose inherent difficulties to performance objectives, which in turn helps the designer specify reasonable goals, and make judicious modifications and revisions on the design. In this process, the theory of fundamental control limitations promises to provide valuable insights and analytical justifications to long-held design heuristics and, indeed, to extend such heuristics further beyond. This has become increasingly more relevant, as modern control design theory and practice relies heavily on optimization-based numerical routines and tools.

Systematic investigation and understanding of fundamental control limitations began with the classical work of Bode in the 1940s on

logarithmic sensitivity integrals, known as the Bode integrals. Bode's work has had a lasting impact on the theory and practice of control and has inspired continued research effort dated most recently, leading to a variety of extensions and new results which seek to quantify design constraints and performance limitations by logarithmic integrals of Bode and Poisson type. On the other hand, the search for the best achievable performance is a natural goal in optimal control problems, which has lend bounds on optimal performance indices defined under various criteria. Likewise, the latter developments have also been substantial and are continuing to branch to different problems and different system categories.

In this entry we attempt to provide a summary overview of the key developments in the study of fundamental limitations of feedback control. While the understanding on this subject has been compelling and the results are rather prolific, we focus on Bode-type integral relations and the best achievable performance limits, two branches of the study that are believed to be most well-developed. Roughly speaking, the Bode-type integrals are most useful for quantifying the inherent design constraints and tradeoffs in the frequency domain, while the performance results provide fundamental limits of canonical control objectives defined using frequency- and time-domain criteria. Invariably, the two sets of results are intimately related and reinforce each other. The essential message then is that despite its many benefits, feedback has its own limitations and is subject to various constraints. Feedback design, for that sake, requires often times a hard tradeoff.

Control Design Specifications

We begin by introducing the basic notation to be used in the sequel. Let $\mathbb{C}_+ := \{z : \text{Re}(z) > 0\}$ denote the open right half plane (RHP) and $\overline{\mathbb{C}}_+$ the closed RHP (CRHP). For a complex number z, we denote its conjugate by $\overline{z}$. For a complex vector x, we denote its conjugate transpose by x^H, and its Euclidean norm by $\|x\|_2$. The largest

singular value of a matrix A will be written as $\overline{\sigma}(A)$. If A is a Hermitian matrix, we denote by $\overline{\lambda}(A)$ its largest eigenvalue. For any unitary vectors $u, v \in \mathbb{C}^n$, we denote by $\angle(u, v)$ the *principal angle* between the two one-dimensional subspaces, called the directions, spanned by u and v:

$$\cos \angle(u, v) := |u^H v|.$$

For a stable continuous-time system with transfer function matrix $G(s)$, we define its $\mathcal{H}_\infty$ norm by

$$\|G\|_\infty := \sup_{\text{Re}(s) > 0} \overline{\sigma}(G(s)).$$

We consider the standard configuration of finite-dimensional linear time-invariant (LTI) feedback control systems given in Fig. 1. In this setup, P and K represent the transfer functions of the plant model and controller, respectively, r is a command signal, d a disturbance, n a noise signal, and y the output response. Define the open-loop transfer function, the sensitivity function, and the complementary sensitivity function by

$$L = PK, \quad S = (I + L)^{-1}, \quad T = L(I + L)^{-1},$$

respectively. Then the output can be expressed as

$$y = Sd - Tn + SPr.$$

The goal of feedback control design is to design a controller K so that the closed-loop system is stable and that it achieves certain performance specifications. Typical design objectives include:

- *Disturbance attenuation*. The effect of the disturbance signal on the output should be kept small, which translates into the require-
Fundamental Limitation of Feedback Control, Fig. 1
Feedback configuration

ment that the sensitivity function be small in magnitude at the frequencies of interest. For a single-input single-output (SISO) system, this mandates that

$$|S(j\omega)| < 1, \quad \forall \, \omega \in [0, \, \omega_1).$$

The sensitivity magnitude $|S(j\omega)|$ is to be kept as small as possible in the low frequency range.

- *Noise reduction.* The noise response should be reduced at the output. This requires that the complementary sensitivity function be small in magnitude at frequencies of interest. For a SISO system, the objective is to achieve

$$|T(j\omega)| < 1, \quad \forall \, \omega \in [\omega_2, \, \infty).$$

Similarly, the magnitude $|T(j\omega)|$ is desired to be the smallest at high frequencies.

Moreover, feedback can be introduced to achieve many other objectives including regulation, command tracking, improved sensitivity to parameter variations, and, more generally, system robustness, all by manipulating the three key transfer functions: the open-loop transfer function, the sensitivity function, and the complementary sensitivity function.

The design and implementation of feedback systems, on the other hand, are also subject to many constraints, which include

1. Causality: A system must be causal for it to be implementable. This constraint requires that no ideal filter can be used for compensation and that the system's relative degree and delay be preserved.
2. Stability: The closed-loop system must be stable. This implies that every closed-loop transfer function must be bounded and analytic in CRHP.
3. Interpolation: There should be no unstable pole-zero cancelation between the plant and controller, in order to rid of hidden instability. Thus, at each RHP pole p_i and zero z_i, it is necessary that

$$S(p_i) = 0, \qquad T(p_i) = 1,$$

$$S(z_i) = 1, \qquad T(z_i) = 0.$$

4. Structural constraints: Constraints in this category arise from the feedback structure itself; for example, $S(s) + T(s) = 1$. The implication then is that the closed-loop transfer functions cannot be independently designed, thus resulting in conflicting design objectives.

For a given plant, each of these constraints is unalterable and hence is fundamental, and each will constrain the performance attainable in one way or another. The question we face then is how the constraints may be captured in a form that is directly pertinent and useful to feedback design.

Bode Integral Relations

In the classical feedback control theory, Bode's gain-phase formula (Bode 1945) is used to express the aforementioned design constraints for SISO systems.

Bode Gain-Phase Integral *Suppose that $L(s)$ has no pole and zero in $\overline{\mathbb{C}}_+$. Then at any frequency ω_0,*

$$\angle L(j\omega_0) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{d \log |L|}{d\nu} \log \coth \frac{|\nu|}{2} d\nu.$$

A special form of the Hilbert transform, this gain-phase formula relates the gain and phase of the open-loop transfer function evaluated along the imaginary axis, whose implication may be explained as follows. In order to make the sensitivity response small in the low frequency range, the open-loop transfer function is required to have a high gain; the higher, the better. On the other hand, for noise reduction and robustness purposes, we need to keep the loop gain low at high frequencies, the lower the better. Evidently, to maximize these objectives, we want the two frequency bands as wide as possible. This then requires a steep decrease of the loop gain and hence a rather negative slope in the crossover region, say, the intermediate frequency range near ω_0. But the gain-phase relationship tells that a very negative derivative in the gain will lead to

a very negative phase, driving the phase closer to the negative 180 degree, namely, the critical point of stability. It consequently reduces the phase margin and may even cause instability. As a result, the gain-phase relationship demonstrates a conflict between the two design objectives. It is safe to claim that much of the classical feedback design theory came as a consequence of this simple relationship, aiming to shape the open-loop frequency response in the crossover region by trial and error, using lead or lag filters.

While in using the gain-phase formula, the design specifications imposed on closed-loop transfer functions are translated approximately into the requirements on the open-loop transfer function, and the tradeoff between different design goals is achieved by shaping the open-loop gain and phase; a more direct vehicle to accomplish this same goal is Bode's sensitivity integral (Bode 1945).

Bode Sensitivity Integrals *Let $p_i \in \mathbb{C}_+$ be the unstable poles and $z_i \in \mathbb{C}_+$ the nonminimum phase zeros of $L(s)$. Suppose that the closed-loop system in Fig. 1 is stable.*

(i) If $L(s)$ has relative degree greater than one, then

$$\int_0^\infty \log |S(j\omega)| d\omega = \pi \sum_i p_i.$$

(ii) If $L(s)$ contains no less than two integrators, then

$$\int_0^\infty \frac{\log |T(j\omega)|}{\omega^2} d\omega = \pi \sum_i \frac{1}{z_i}.$$

Bode's original work concerns the sensitivity integral for open-loop stable systems only. The integral relations shown herein, which are attributed to Freudenberg and Looze (1985) and Middleton (1991), respectively, provide generalizations to open-loop unstable and nonminimum phase systems.

Why are Bode sensitivity integrals important? What is the hidden message behind the mathematical formulas? Simply put, Bode integral exhibits that a feedback system's sensitivity must

abide some kind of conservation law, or invariance property: the integral of the logarithmic sensitivity magnitude over the entire frequency range must be a nonnegative constant, determined by the open-loop unstable poles. This property mandates a tradeoff between sensitivity reduction and sensitivity amplification in different frequency bands. Indeed, to achieve disturbance attenuation, the logarithmic sensitivity magnitude must stay below zero db, the lower the better. For noise reduction and robustness, however, its tail has to roll off sufficiently fast to zero db at high frequencies. Since, in light of the integral relation, the total area under the logarithmic magnitude curve is nonnegative, the logarithmic magnitude must rise above zero db, so that under its curve, the positive and negative areas may cancel each other to yield a nonnegative value. As such, an undesirable sensitivity amplification occurs, resulting in a fundamental tradeoff between the desirable sensitivity reduction and the undesirable sensitivity amplification, known colloquially as the *waterbed effect*.

MIMO Integral Relations

For a multi-input multi-output (MIMO) system depicted in Fig. 1, the sensitivity and complementary sensitivity functions, which now are transfer function matrices, satisfy similar interpolation constraints: at each RHP pole p_i and zero z_i of $L(s)$, the equations

$$S(p_i)\eta_i = 0, \qquad T(p_i)\eta_i = \eta_i,$$

$$w_i^H S(z_i) = w_i^H, \qquad w_i^H T(z_i) = 0$$

hold with some unitary vectors η_i and w_i, where η_i is referred to as a *right pole direction vector* associated with p_i, and w_i a *left zero direction vector* associated with z_i.

While it seems both natural and tempting, the extension of Bode integrals to MIMO systems has been highly nontrivial a task. Deep at the root is the complication resulted from the directionality properties of MIMO systems. Unlike in a SISO

system, the measure of frequency response magnitude is now the largest singular value of a transfer function matrix, which represents the worst-case amplification of energy-bounded signals, a direct counterpart to the gain of a scalar transfer function. This fact alone proves to cast a fundamental difference and poses a formidable obstacle. From a technical standpoint, the logarithmic function of the largest singular value is no longer a harmonic function as in the SISO case, but only a subharmonic function. Much to our regret then, familiar tools found from analytic function theory, such as Cauchy and Poisson theorems, the very backbone in developing Bode integrals, cease to be applicable. Nevertheless, it remains possible to extend Bode integrals in their essential spirit. Advances are made by Chen (1995, 1998, 2000).

MIMO Bode Sensitivity Integrals *Let $p_i \in \mathbb{C}_+$ be the unstable poles of $L(s)$ and $z_i \in \mathbb{C}_+$ the nonminimum phase zeros of $L(s)$. Suppose that the closed-loop system in Fig. 1 is stable.*

(i) If $L(s)$ has relative degree greater than one, then

$$\int_0^\infty \log \overline{\sigma}(S(j\omega))d\omega \geq \pi\overline{\lambda}\left(\sum_i p_i \eta_i \eta_i^H\right).$$

(ii) If $L(s)$ contains no less than two integrators, then

$$\int_0^\infty \frac{\log \overline{\sigma}(T(j\omega))}{\omega^2}d\omega \geq \pi\overline{\lambda}\left(\sum_i \frac{1}{z_i}w_i w_i^H\right)$$

where η_i and w_i are some unitary vectors related to the right pole direction vectors associated with p_i and the left zero direction vectors associated with z_i, respectively.

From these extensions, it is evident that same limitations and tradeoffs on the sensitivity and complementary sensitivity functions carry over to MIMO systems; in fact, both integrals reduce to the Bode integrals when specialized to

SISO systems. Yet there is something additional and unique of MIMO systems: the integrals now depend on not only the locations but also the directions of the zeros and poles. In particular, it can be shown that they depend on the mutual orientation of these directions, and the dependence can be explicitly characterized geometrically by the principal angles between the directions. This new phenomenon, which finds no analog in SISO systems, thus highlights the important role of directionality in sensitivity tradeoff and more generally, in the design of MIMO systems.

A more sophisticated and accordingly, more informative variant of Bode integrals is the Poisson integral for sensitivity and complementary sensitivity functions (Freudenberg and Looze 1985), which can be used to provide quantitative estimates of the waterbed effect. MIMO versions of Poisson integrals are also available (Chen 1995, 2000).

Frequency-Domain Performance Bounds

Performance bounds complement the integral relations and provide fundamental thresholds to the best possible performance ever attainable. Such bounds are useful in providing benchmarks for evaluating a system's performance prior to and after controller design. In the frequency domain, fundamental limits can be specified as the minimal peak magnitude of the sensitivity and complementary sensitivity functions achievable by feedback, or formally, the minimal achievable $\mathcal{H}_\infty$ norms:

$$\gamma_{\min}^S := \inf\{\|S(s)\|_\infty : K(s) \text{ stabilizes } P(s)\},$$

$$\gamma_{\min}^T := \inf\{\|T(s)\|_\infty : K(s) \text{ stabilizes } P(s)\}.$$

Drawing upon *Nevanlinna-Pick interpolation* theory for analytic functions, one can obtain exact performance limits under rather general circumstances (Chen 2000).

$\mathcal{H}_\infty$ **Performance Limits** *Let $z_i \in \mathbb{C}_+$ be the nonminimum phaze zeros of $P(s)$ with left direction vectors w_i, and $p_i \in \mathbb{C}_+$ the unstable poles*

of $P(s)$ with right direction vectors η_i, where z_i and p_i are all distinct. Then,

$$\gamma_{\min}^S = \gamma_{\min}^T = \sqrt{1 + \overline{\sigma}^2 \left(Q_p^{-1/2} Q_{zp} Q_z^{-1/2} \right)},$$

where Q_z, Q_p, and Q_{zp} are the matrices given by

$$Q_z := \left[\frac{w_i^H w_j}{z_i + \overline{z}_j} \right], \quad Q_p := \left[\frac{\eta_i^H \eta_j}{\overline{p}_i + p_j} \right],$$

$$Q_{zp} := \left[\frac{w_i^H \eta_j}{z_i - p_j} \right].$$

More explicit bounds showing how zeros and poles may interact to have an effect on these limits can be obtained, e.g., as

$$\gamma_{\min}^S = \gamma_{\min}^T \geq$$
$$\sqrt{\sin^2 \angle(w_i, \eta_j) + \left| \frac{p_j + \overline{z_i}}{p_j - z_i} \right|^2 \cos^2 \angle(w_i, \eta_j)},$$

which demonstrates once again that the pole and zero directions play an important role in MIMO systems. Note that for RHP poles and zeros located in the close vicinity, this bound can become excessively large, which serves as another vindication why unstable pole-zero cancelation must be prohibited. Note also that for MIMO systems however, whether near pole-zero cancelation is problematic depends additionally on the mutual orientation of the pole and zero directions.

Tracking and Regulation Limits

Tracking and regulation are two canonical objectives of servo mechanisms and constitute chief criteria in assessing the performance of feedback control systems. Understandings gained from these problems will shed light into more general issues indicative of feedback design. In its full generality, a tracking system can be depicted as in Fig. 2, in which a 2-DOF (degree of freedom) controller K is to be designed for

the output z to track a given reference input r, based on the feedforward of the reference signal r and the feedback of the measured output y. The tracking performance is defined in the time domain by the integral square error

$$J = \int_0^\infty \|z(t) - r(t)\|_2^2 dt,$$

Typically, we take r to be a step signal, which in the MIMO setting corresponds to a unitary constant vector, i.e., $r(t) = v$, $t > 0$ and $r(t) = 0$, $t < 0$, where $\|v\|_2 = 1$. We assume P to be LTI. But K can be arbitrarily general, as long as it is causal and stabilizing. We want z to not only track r asymptotically but also minimize J. But how small can it be?

For the regulation problem, a general setup is given in Fig. 3. Likewise, K may be taken as a 2-DOF controller. The control output energy is measured by the quadratic cost

$$E = \int_0^\infty \|u(t)\|_2^2 dt.$$

We consider a disturbance signal d, typically taken as an impulse signal, $d(t) = v\delta(t)$, where v is a unitary vector. In this case, the disturbance can be interpreted as a nonzero initial condition, and the controller K is to regulate the system's zero-input response. Similarly, we assume that P
Fundamental Limitation of Feedback Control, Fig. 2
2-DOF tracking control structure
Fundamental Limitation of Feedback Control, Fig. 3
2-DOF regulator

is LTI, but allow K to be any causal, stabilizing controller. Evidently, for a stable P, the problem is trivial; the response will restore itself to the origin and thus no energy is required. But what if the system is unstable? How much energy does the controller must generate to combat the disturbance? What is the smallest amount of energy required? These questions are answered by the best achievable limits of the tracking and regulation performance (Chen et al. 2000, 2003).

Tracking and Regulation Performance Limits
Let $p_i \in \mathbb{C}_+$ and $z_i \in \mathbb{C}_+$ be the RHP poles and zeros of $P(s)$, respectively. Then,

$$\inf\{E : K \text{ stabilizes } P(s)\} = \sum_i p_i \cos^2(\zeta_i, v),$$

$$\inf\{J : K \text{ stabilizes } P(s)\} = \sum_i \frac{1}{z_i} \cos^2(\xi_i, v),$$

where ζ_i and ξ_i are some unitary vectors related to the right pole direction vectors associated with p_i and the left zero direction vectors associated with z_i, respectively.

It becomes instantly clear that the optimal performance depends on both the pole/zero locations and their directions. In particular, it depends on the mutual orientation between the input and pole/zero directions. This sheds some interesting light. Take the tracking performance for an example. For a SISO system, the minimal tracking error can never be made zero for a nonminimum phase plant; in other words, perfect tracking can never be achieved. Yet this is possible for MIMO systems, when the input and zero directions are appropriately aligned, specifically when they are orthogonal. Interestingly, the optimal performance in both cases can be achieved by LTI controllers, though allowed to be more general. As a result, the results herein provide the true fundamental limits that cannot be further improved, in spite of using any other more general forms such as nonlinear, time-varying feedforward and feedback. It is simply the best one can ever hope for, and the LTI controllers turn out to be optimal.

Summary and Future Directions

Whether in time or frequency domain, while the results presented herein may differ in forms and contexts, they unequivocally point to the fact that inherent constraints exist in feedback design, and fundamental limitations will necessarily arise, limiting the performance achievable regardless of controller design. Such constraints and limitations are especially exacerbated by the nonminimum phase zeros and unstable poles in the system. Understanding of these constraints and limitations proves essential to the success of control design.

For both its intrinsic appeal and fundamental implications, the study of fundamental control limitations will continue to be a topic of enduring vitality and indeed will prove timeless. Challenges are especially daunting and endeavor is called for, e.g., to incorporate information and communication constraints into control limitation studies, of which networked control and multi-agent systems serve as notable testimonies.

Game Theory for Security

Tansu Alpcan

Engineering, The University of Melbourne,
Melbourne, Australia

Abstract

Game theory provides a mature mathematical foundation for making security decisions in a principled manner. Security games help formalizing security problems and decisions using quantitative models. The resulting analytical frameworks lead to better allocation of limited resources and result in more informed responses to security problems in complex systems and organizations. The game-theoretic approach to security is applicable to a wide variety of systems and critical infrastructures such as electricity, water, financial services, and communication networks.

Keywords

Complex systems; Cyberphysical system security; Game theory; Security games

Introduction

Securing a system involves making numerous decisions whether the system is a computer network, part of a business process in an organization, or belongs to a critical infrastructure. One has to decide on, for example, how to configure sensors for surveillance, collect further information on system properties, allocate resources to secure a critical segment, or who should be able to access a specific function in the system. The decision-maker can be, depending on the setting, a regular employee, a system administrator, or the chief technical officer of an organization. In many cases, the decisions are made automatically by a computer program such as allowing a packet pass the firewall or filtering it out. The time frame of these decisions exhibits a high degree of variability from milliseconds, if made by software, to days and weeks, e.g., when they are part of a strategic plan. Each security decision has a cost and any decision-maker is always constrained by limited amount of available resources. More importantly, each decision carries a security risk that needs to be taken into account when balancing the costs and the benefits.

Security games facilitate building analytical models which capture the interaction between malicious attackers, who aim to compromise networks, and owners or administrators defending them. Attacks exploiting vulnerabilities of the underlying systems and defensive countermeasures constitute the moves of the game. Thus, the strategic struggle between attackers and defenders is formalized quantitatively based on the solid mathematical foundation provided by the field of game theory.

An important aspect of security games is the allocation of limited available resources from the perspectives of both attackers and defenders. If the players had access to unlimited resources (e.g., time, computing power, bandwidth), then the resulting security games would be trivial. In real-world security settings, however, both attackers and defenders have to act strategically and make numerous decisions when allocating their respective resources. Unlike in an optimization approach, security games take into account the decisions and resource limitations of both the attackers and the defenders.
Security Games

A security game is defined with four components: the players, the set of possible actions or strategies for each player, the outcome of the game for each player as a result of their action-reaction, and information structures in the game. The players have their own (selfish or malicious) motivations and inherent resource constraints. Based on these motivations and information available, they choose the most beneficial strategies for themselves and act accordingly. Hence, game theory helps analyzing decision-makers interacting on a system in a quantitative manner.

An Example Formulation

A simple security game can be formulated as a two-player and strategic (noncooperative) one, where one player is the *attacker* and the other one is the *defender* protecting a system. Let the discrete actions available to the attacker and the defender be $\{a, b\}$ and $\{c, d\}$, respectively. Each attack-defense pair leads to one of the outcome pairs for the attacker and the defender $\{(x1, y1), (x2, y2), (x3, y3), (x4, y4)\}$, which represent the respective player's gains (or losses). This security game is depicted graphically in Fig. 1. It can also be represented as a matrix game as follows, where the attacker is the row player and the defender is the column player:

$$
\begin{array}{cc}
(c) & (d) \\
\begin{bmatrix} (x1, y1) & (x2, y2) \\ (x3, y3) & (x4, y4) \end{bmatrix} & \begin{array}{c} (a) \\ (b) \end{array}
\end{array}
$$

Game Theory for Security, Fig. 1 A simple, two-player security game

If the decision variables of the players are continuous, for example, $x \in [0, a]$ and $y \in [0, c]$ denote attack and defense intensity, respectively, then the resulting continuous-kernel game is described using functions instead of a matrix. Then, $J^{\text{attacker}}(x, y)$ and $J^{\text{defender}}(x, y)$ quantify the cost of the attacker and defender as a function of their actions, respectively.

Security Game Types

In its simplest formulation, the conflict between those defending a system and malicious attackers targeting it can be modeled as a two-person zero-sum security game, where the loss of a player is the gain of the other. Alternatively, two- and multi-person nonzero-sum security games generalize this for capturing a broader range of interactions. Static game formulations and their repeated versions are helpful for modeling myopic behavior of players in fast changing situations where planning future actions is of little use. In the case where the underlying system dynamics are predictable and available to the players, dynamic security game formulations can be utilized. If there is an order of actions in the game, for example, a purely reactionary defender, then leader-follower games can be used to formulate such cases where the attacker takes the lead and the defender follows.

Within the framework of security games, the concept of Nash equilibrium, where no player gains from deviating from its own Nash equilibrium strategy if others stick with theirs, provides a solid foundation. However, there are refinements and additional solution concepts when the game is dynamic or when there is more than one

Nash equilibrium or information limitations in the game. These constitute an open and ongoing research topic. A related research question is the design of security games to ensure a favorable outcome from a global perspective while taking into account the independence of individual players in their decisions.

In certain cases, it is useful to analyze the player interactions in multiple layers. For example, in some security games there may be defenders and malicious attackers trying to influence a population of other players by indirect means. In order to circumvent modeling complexity of the problem, evolutionary games have been suggested. While evolutionary games forsake modeling individual player actions, they provide valuable insights to collective behavior of populations of players and ensure tractability. Such models are useful, for example, in the analysis of various security policies affecting many users or security of large-scale critical systems.

Another important aspect of security decisions is the availability and acquisition of information on the properties of the system at hand, the actions of other players, and the incentives behind them. Clearly, the amount of information available has a direct influence on the decisions, yet acquiring information is often costly or even infeasible in some cases. Then, the decisions have to be made with partial information, and information collection becomes part of the decision process itself, creating a complex feedback loop.

Statistical or machine learning techniques and system identification are other useful methods in the analysis of security games where players use the acquired information iteratively to update their own model of the environment and other players. The players then decide on their best courses of action. Existing work on fictitious play and reinforcement learning methods such as Q-learning are applicable and useful. A unique feature of security games is the fact that players try to hide their actions from others. These observability issues and distortions in observations can be captured by modeling the interaction between players who observe each other's actions as a noisy communication channel.

Applications

An early application of the decision and game-theoretic approach has been to the well-defined jamming problem, where malicious attackers aim to disrupt wireless communication between legitimate parties (Kashyap et al. 2004; Zander 1990). Detection of security intrusion and anomalies due to attacks is another problem, where the interaction between attackers and defenders has been modeled successfully using game theory (Alpcan and Başar 2011; Kodialam and Lakshman 2003). Decision and game-theoretic approaches have been applied to a broad variety of networked system security problems such as security investments in organizations (Miura-Ko et al. 2008), (location) privacy (Buttyan and Hubaux 2008; Kantarcioglu et al. 2011), distributed attack detection, attack trees and graphs, adversarial control (Altman et al. 2010), network path selection (Zhang et al. 2010) and topology planning in presence of adversaries (Gueye et al. 2010), as well as to other types of security games and decisions. More recently, security games have been used to investigate cyberphysical security of (smart) power grid (Law et al. 2012). The proceedings of the last three Conferences on Decision and Game Theory for Security published as edited volumes in 2010 (Alpcan et al. 2010), 2011 (Baras et al. 2011), and 2012 (Grossklags and Walrand 2012) as well as the recent survey paper (Manshaei et al. 2013) present an extensive segment of the literature on the subject.

Analytical risk management is a related emerging research subject. Analytical methods and game theory have been applied to the field only recently but with increasing success (Guikema 2009; Mounzer et al. 2010). Another emerging topic is the adversarial mechanism design (Chorppath and Alpcan 2011; Roth 2008), where the goal is to design mechanisms resistant to malicious behavior.

Summary and Future Directions

Game theory provides quantitative methods for studying the players in security problems such

as attackers, defenders, and users as well as their interaction and incentives. Hence, it facilitates making decisions on the best courses of action in addressing security problems while taking into account resource limitations, underlying incentive mechanisms, and security risks. Thus, security games and associated quantitative models have started to replace the prevalent ad hoc decision processes in a wide variety of security problems from safeguarding critical infrastructure to risk management, trust, and privacy in networked systems.

Game theory for security is a young and active research area as evidenced by the recently initiated conference series "Conference on Decision and Game Theory for Security" (www.gamesec-conf.org), the increasing number of journal and conference articles, as well as the recently published books (Alpcan and Başar 2011; Buttyan and Hubaux 2008; Tambe 2011).

Game Theory: Historical Overview

Tamer Başar
Coordinated Science Laboratory, University of Illinois, Urbana, IL, USA

Abstract

This article provides an overview of the aspects of game theory that are covered in this *Encyclopedia*, which includes a broad spectrum of topics on static and dynamic game theory. It starts with a brief overview of game theory, identifying its basic ingredients, and continues with a brief historical account of the development and evolution of the field. It concludes by providing pointers to other articles in the *Encyclopedia* on game theory, and a list of references.

Keywords

What Is Game Theory?

Game theory deals with strategic interactions among multiple decision makers, called *players* (and in some context *agents*), with each player's preference ordering among multiple alternatives captured in an objective function for that player, which she either tries to maximize (in which case the objective function is a *utility* function or a *benefit* function) or minimize (in which case we refer to the objective function as a *cost* function or a *loss* function). For a nontrivial game, the objective function of a player depends on the choices (*actions* or equivalently *decision variables*) of at least one other player, and generally of all the players, and hence a player cannot simply optimize her own objective function independent of the choices of the other players. This thus brings in a coupling among the actions of the players and binds them together in decision making even in a noncooperative environment. If the players are able to enter into a cooperative agreement so that the selection of actions or decisions is done collectively and with full trust, so that all players would benefit to the extent possible, then we would be in the realm of *cooperative game theory*, where issues such as bargaining and characterization of *fair* outcomes, coalition formation, and excess utility distribution are of relevance; an article in this *Encyclopedia* (by Haurie) discusses cooperation and cooperative outcomes in the context of dynamic games. Other aspects of cooperative game theory can be found in several standard texts on game theory, such as Owen (1995), Vorob'ev (1977), or Fudenberg and Tirole (1991). See also the 2009 survey article Saad et al. (2009), which emphasizes applications of cooperative game theory to communication networks.

If no cooperation is allowed among the players, then we are in the realm of *noncooperative game theory*, where first one has to introduce a satisfactory solution concept. Leaving aside for the moment the issue of how the players can

reach such a solution point, let us address the issue of what would be the minimum features one would expect to see there. To first order, such a solution point should have the property that if all players but one stay put, then the player who has the option of moving away from the solution point should not have any incentive to do so because she cannot improve her payoff. Note that we cannot allow two or more players to move collectively from the solution point, because such a collective move requires cooperation, which is not allowed in a noncooperative game. Such a solution point where none of the players can improve her payoff by a unilateral move is known as a *noncooperative equilibrium* or *Nash equilibrium*, named after John Nash, who introduced it and proved that it exists in finite games (i.e., games where each player has only a finite number of alternatives), over 60 years ago; see Nash (1950, 1951). This result and its various extensions for different frameworks as well as its computation (both off-line and online) are discussed in several articles in this *Encyclopedia*. Another noncooperative equilibrium solution concept is the *Stackelberg equilibrium*, introduced in von Stackelberg (1934), and predating the Nash equilibrium, where there is a hierarchy in decision making among the players, with some of the players, designated as *leaders*, having the ability to first announce their actions (and make a commitment to play them) and the remaining players, designated as *followers*, taking these actions as given in the process of computation of their noncooperative (Nash) equilibria (among themselves). Before announcing their actions, the leaders would of course anticipate these responses and determine their actions in a way that the final outcome will be most favorable to them (in terms of their objective functions). For a comprehensive treatment of Nash and Stackelberg equilibria for different classes of games, see Başar and Olsder (1999).

We say that a noncooperative game is *nonzero-sum* if the sum of the players' objective functions cannot be made zero after appropriate positive scaling and/or translation that do not depend on the players' decision variables. We say that a two-player game is *zero-sum* if the sum of the objective functions of the two players is *zero* or can be made zero by appropriate positive scaling and/or translation that do not depend on the decision variables of the players; hence, two-player zero-sum games can be viewed as a special subclass of two-player nonzero-sum games, and in this case the Nash equilibrium becomes the *saddle-point equilibrium*. A game is a *finite game* if each player has only a finite number of alternatives, that is, the players pick their actions out of finite sets (action sets); otherwise, the game is an *infinite game*. Finite games are also known as *matrix games*. An infinite game is said to be a *continuous-kernel game* if the action sets of the players are continua and the players' objective functions are continuous with respect to action variables of all players. A game is said to be *deterministic* if the players' actions uniquely determine the outcome, as captured in the objective functions, whereas if the objective function of at least one player depends on an additional variable (state of nature) with a probability distribution known to all players (or can be learned on line), then we have a *stochastic game*. A game is a *complete information* game if the description of the game (i.e., the players, the objective functions, and the underlying probability distributions (if stochastic)) is common information to all players; otherwise, we have an *incomplete information* game. We say that a game is *static* if players have access to only the a priori information (shared by all) and none of the players has access to information on the actions of any of the other players; otherwise, what we have is a *dynamic game*. A game is a *single-act game* if every player acts only once; otherwise, the game is *multi-act*. Note that it is possible for a single-act game to be dynamic and for a multi-act game to be static. A dynamic game is said to be a *differential game* if the evolution of the decision process (controlled by the players over time) takes place in continuous time and generally involves a differential equation; if it takes place over a discrete-time horizon, the dynamic game is sometimes called a *discrete-time game*.

In dynamic games, as the game progresses players acquire information (complete or partial)

on past actions of other players and use this information in selecting their own actions (also dictated by the equilibrium solution concept at hand). In finite dynamic games, for example, the progression of a game involves a *tree structure* (also called *extensive form*) where each node is identified with a player along with the time when she acts, and branches emanating from a node show the possible moves of that particular player. A player, at any point in time, could generally be at more than one node, which is a situation that arises when the player does not have complete information on the past moves of other players and hence may not know with certainty which particular node she is at at any particular time. This uncertainty leads to a clustering of nodes into what is called *information sets* for that player. What players decide on within the framework of the extensive form is not their actions, but their *strategies*, that is, what action they would take at each information set (in other words, correspondences between their information sets and their allowable actions). They then take specific actions (or actions are executed on their behalf), dictated by the strategies chosen as well as the progression of the game (decision) process along the tree. The equilibrium is then defined in terms of not actions but strategies.

The notion of a *strategy*, as a mapping from the collection of information sets to action sets, extends readily to infinite dynamic games, and hence, in both differential games and difference games, Nash equilibria are defined in terms of strategies. Several articles in this *Encyclopedia* discuss such equilibria, for both zero-sum and nonzero-sum dynamic games, with and without the presence of probabilistic uncertainty.

In the broad scheme of things, game theory and particularly noncooperative game theory can be viewed as an extension of two fields, both covered in this *Encyclopedia*: *Mathematical Programming* and *Optimal Control Theory*. Any problem in game theory collapses to a problem in one of these disciplines if there is only one player. One-player static games are essentially mathematical programming problems (linear programming or nonlinear programming), and

one-player difference or differential games can be viewed as optimal control problems.

Highlights on the History and Evolution of Game Theory

Game theory has enjoyed over 70 years of scientific development, with the publication of the *Theory of Games and Economic Behavior* by von Neumann and Morgenstern (1947) generally acknowledged to *kick-start* the field. It has experienced incessant growth in both the number of theoretical results and the scope and variety of applications. As a recognition of the vitality of the field, through 2012 a total of 10 Nobel Prizes were given in Economic Sciences for work primarily in game theory, with the first such recognition bestowed in 1994 on John Harsanyi, John Nash, and Reinhard Selten "for their pioneering analysis of equilibria in the theory of noncooperative games." The second round of Nobel Prizes in game theory went to Robert Aumann and Thomas Schelling in 2005, "for having enhanced our understanding of conflict and cooperation through game-theory analysis." The third round recognized Leonid Hurwicz, Eric Maskin, and Roger Myerson in 2007, "for having laid the foundations of mechanism design theory." And the most recent one was in 2012, recognizing Alvin Roth and Lloyd Shapley, "for the theory of stable allocations and the practice of market design." To this list of highest-level awards related to contributions to game theory, one should also add the 1999 Crafoord Prize (which is the highest prize in Biological Sciences), which went to John Maynard Smith (along with Ernst Mayr and G. Williams) "for developing the concept of evolutionary biology," where Smith's recognized contributions had a strong game-theoretic underpinning, through his work on evolutionary games and evolutionary stable equilibrium (Smith 1974, 1982; Smith and Price 1973); this is the topic of one of the articles in this *Encyclopedia* (by Altman). Several other "game theory" articles in the *Encyclopedia* also relate to the

contributions of the Nobel Laureates mentioned above.

Even though von Neumann and Morgenstern's 1944 book is taken as the starting point of the scientific approach to game theory, game-theoretic notions and some isolated key results date back to earlier years and even centuries. Sixteen years earlier, in 1928, von Neumann himself had resolved completely an open fundamental problem in zero-sum games, that *every finite two-player zero-sum game admits a saddle point in mixed strategies*, which is known as the *Minimax Theorem* (von Neumann 1928) – a result which Emile Borel had conjectured to be false eight years before. Some early traces of game-theoretic thinking can be seen in the 1802 work (*Considérations sur la théorie mathématique du jeu*) of André-Marie Ampère (1775–1836), who was influenced by the 1777 writings (Essai d'Arithmétique Morale) of Georges Louis Buffon (1707–1788).

Which event or writing has really started game-theoretic thinking or approach to decision making (in law, politics, economics, operations research, engineering, etc.) may be a topic of debate, but what is indisputable is that in (zero-sum) differential games (which is most relevant to control theory) the starting point was the work of Rufus Isaacs in the RAND Corporation in the early 1950s, which remained classified for at least a decade, before being made accessible to a broad readership in 1965 (Isaacs 1965); see also the review (Ho 1965) which first introduced the book to the control community. One of the articles in this *Encyclopedia* (by Bernhard) talks about this history and the theory developed by Isaacs, within the context of pursuit-evasion games, and another article (again by Bernhard) discusses the impact the zero-sum differential game framework has made on robust control design (Başar and Bernhard 1995). Extension of the game-theoretic framework to nonzero-sum differential games with Nash equilibrium as the solution concept was initiated in Starr and Ho (1969) and with Stackelberg equilibrium as the solution concept in Simaan and Cruz (1973). Systematic study of the role information structures play in the existence of such equilibria

and their uniqueness or nonuniqueness (termed *informational nonuniqueness*) was carried out in Başar (1974, 1976, 1977).

Related Articles on Game Theory in the Encyclopedia

Several articles in the *Encyclopedia* introduce various subareas of game theory and discuss important developments (past and present) in each corresponding area.

The article ▶ Strategic Form Games and Nash Equilibrium introduces the static game framework along with the Nash equilibrium concept, for both finite and infinite games, and discusses the issues of existence and uniqueness as well efficiency. The article ▶ Dynamic Noncooperative Games focuses on dynamic games, again for both finite and infinite games, and discusses extensive form descriptions of the underlying dynamic decision process, either as trees (in finite games) or difference equations (in discrete-time infinite games). Bernhard, in two articles, discusses continuous-time dynamic games, described by differential equations (so-called differential games), but in the two-person zero-sum case. One of these articles ▶ Pursuit-Evasion Games and Zero-Sum Two-Person Differential Games describes the framework initiated by Isaacs, and several of its extensions for pursuit-evasion games, and the other one ▶ Linear Quadratic Zero-Sum Two-Person Differential Games presents results on the special case of linear quadratic differential games, with an important application of that framework to robust control and more precisely H^∞-optimal control.

When the number of players in a nonzero-sum game is countably infinite, or even just sufficiently large, some simplifications arise in the computation and characterization of Nash equilibria. The mathematical framework applicable to this context is provided by *mean field theory*, which is the topic of the article ▶ Mean Field Games, which discusses this relatively new theory within the context of stochastic differential games.

Cooperative solution concepts for dynamic games are discussed in the article ▶ Cooperative Solutions to Dynamic Games, which introduces Pareto optimality, the bargaining solution concept by Nash, characteristic functions, core, and C-optimality, and presents some selected results using these concepts. In the article ▶ Evolutionary Games, the foundations of, as well as the recent advances in, evolutionary games are presented, along with examples showing their potential as a tool for capturing and modeling interactions in complex systems.

The article ▶ Learning in Games addresses the online computation of Nash equilibrium through an iterative process which takes into account each player's response to choices made by the remaining players, with built-in learning and adaptation rules; one such scheme that is discussed in the article is the well-known *fictitious play*. Learning is also the topic of the article ▶ Stochastic Games and Learning, which presents a framework and a set of results using the stochastic games formulation introduced by Shapley in the early 1950s.

The article ▶ Network Games shows how game theory plays an important role in modeling interactions between entities on a network, particularly communication networks, and presents a simple mathematical model to study one such instance, namely, resource allocation in the Internet. How to design a game so as to obtain a desired outcome (as captured by say a Nash equilibrium) is a question central to mechanism design, which is covered in the article ▶ Mechanism Design, which discusses as a specific example the Vickrey-Clarke-Groves (VCG) mechanism.

Two other applications of game theory are to design of auctions and security. The article ▶ Auctions addresses the former, discussing general auction theory along with equilibrium strategies and more specifically combinatorial auctions. The latter is addressed in the article ▶ Game Theory for Security, which discusses how the game-theoretic approach leads to more effective responses to security in complex systems and organizations, with applications to a wide variety of systems and critical infrastructures such as electricity, water, financial services, and communication networks.

Future of Game Theory

The second half of the twentieth century was a golden era for game theory, and all evidence so far in the twenty-first century indicates that the next half century is destined to be a *platinum* era. In all respects game theory is on an upward slope in terms of its vitality, the wealth of topics that fall within its scope, the richness of the conceptual framework it offers, the range of applications, and the challenges it presents to an inquisitive mind.

Generalized Finite-Horizon Linear-Quadratic Optimal Control

Augusto Ferrante[1] and Lorenzo Ntogramatzidis[2]
[1]Dipartimento di Ingegneria dell'Informazione, Università di Padova, Padova, Italy
[2]Department of Mathematics and Statistics, Curtin University, Perth, WA, Australia

Abstract

The linear-quadratic (LQ) problem is the prototype of a large number of optimal control problems, including the fixed endpoint, the point-to-point, and several H_2/H_∞ control problems, as well as the dual counterparts. In the past 50 years, these problems have been addressed using different techniques, each tailored to their specific structure. It is only in the last 10 years that it was recognized that a unifying framework is available. This framework hinges on formulae that parameterize the solutions of the Hamiltonian differential equation in the continuous-time case and the solutions of the extended symplectic system in the discrete-time case. Whereas traditional techniques involve the solutions of Riccati differential or difference equations, the formulae used here to solve the finite-horizon LQ control problem only rely on solutions of the algebraic Riccati equations. In this article, aspects of the framework are described within a discrete-time context.

Cyclic boundary conditions; Discrete-time linear systems; Fixed end-point; Initial value; Point-to-point boundary conditions; Quadratic cost; Riccati equations

Introduction

Ever since the *linear-quadratic* (LQ) optimal control problem was introduced in the 1960s by Kalman in his pioneering paper (1960), it has found countless applications in areas such as chemical process control, aeronautics, robotics, servomechanisms, and motor control, to name but a few.

For details on the *raisons d'être* of LQ problems, readers are referred to the classical textbooks on this topic (Anderson and Moore 1971; Kwakernaak and Sivan 1972) and to the Special Issue on LQ optimal control problems in *IEEE Trans. Aut. Contr.*, vol. AC-16, no. 6, 1971. The LQ regulator is not only important per se. It is also the prototype of a variety of fundamental optimization problems. Indeed, several optimal control problems that are extremely relevant in

practice can be recast into composite LQ, dual LQ, or generalized LQ problems. Examples include LQG, H_2 and H_∞ problems, and Kalman filtering problems. Moreover, LQ optimal control is intimately related, via matrix Riccati equations, to absolute stability, dissipative networks, and optimal filtering. The importance of LQ problems is not restricted to linear systems. For example, LQ control techniques can be used to modify an optimal control law in response to perturbations in the dynamics of a nonlinear plant. For these reasons, the LQ problem is universally regarded as a cornerstone of modern control theory.

In its simplest and most classical version, the finite-horizon discrete LQ optimal control can be stated as follows:

Problem 1 Let $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$, and consider the linear system

$$x_{t+1} = A x_t + B u_t, \quad y_t = C x_t + D u_t, \quad (1)$$

where the initial state $x_0 \in \mathbb{R}^n$ is given. Let $W = W^\top \in \mathbb{R}^{n \times n}$ be positive semidefinite. Find a sequence of inputs u_t, with $t = 0, 1, \ldots, N-1$, minimizing the cost function

$$J_{N,x_0}(u) \overset{\text{def}}{=} \sum_{t=0}^{N-1} \|y_t\|^2 + x_N^\top W x_N. \quad (2)$$

Historically, LQ problems were first introduced and solved by Kalman in (1960). In this paper, Kalman showed that the LQ problem can be solved for *any* initial state x_0, and the optimal control can be written as a state feedback $u(t) = K(t) x(t)$, where $K(t)$ can be found by solving a famous quadratic matrix difference equation known as the *Riccati equation*. When W is no longer assumed to be positive semidefinite, the optimal solution may or may not exist. A complete analysis of this case has been worked out in Bilardi and Ferrante (2007). In the infinite-horizon case (i.e., when N is infinite), the optimal control (when it exists) is stationary and may be computed by solving an *algebraic* Riccati equation (Anderson and Moore 1971; Kwakernaak and Sivan 1972).

Since its introduction, the original formulation of the classic LQ optimal control problem has been generalized in several different directions, to accommodate for the need of considering more general scenarios than the one represented by Problem 1. Examples include the so-called fixed endpoint LQ, in which the extreme states are sharply assigned, and the *point-to-point* case, in which the initial and terminal values of an output of the system are constrained to be equal to specified values. This led to a number of contributions in the area where different adaptations of the Riccati theory were tailored to these diversified contexts of LQ optimal control. These variations of the classic LQ problem are becoming increasingly important due to their use in several applications of interest. Indeed, many applications including spacecraft, aircraft, and chemical processes involve maneuvering between two states during some phases of a typical mission. Another interesting example is the H_2-optimization of transients in switching plants, where the problem can be divided into a set of finite-horizon LQ problems with welding conditions on the optimal arcs for each switch instant. This problem has been the object of a large number of contributions in the recent literature, under different names: Parameter varying systems, jump linear systems, switching systems, and bumpless systems are definitions extensively used to denote different classes of systems affected by sensible changes in their parameters or structures (Balas and Bokor 2004). In recent years, a new unified approach emerged in Ferrante et al. (2005), Ferrante and Ntogramatzidis (2005), Ferrante and Ntogramatzidis (2007a), and Ferrante and Ntogramatzidis (2007b) that solves the finite-horizon LQ optimal control problem via a formula which parameterizes the set of trajectories generated by the corresponding Hamiltonian differential equation in the continuous time and the extended symplectic difference equation in the discrete case. Loosely, we can say that the expressions parameterizing the trajectories of the Hamiltonian differential equation and the extended symplectic difference equation using this approach hinge on a pair of

"opposite" solutions of the associated algebraic Riccati equations. This active stream of research considerably enlarged the range of optimal control problems that can be successfully addressed. This point of view always requires some controllability-type assumption and the extended symplectic pencil (Ferrante and Ntogramatzidis 2005, 2007b) to be regular and devoid of generalized eigenvalues on the unit circle. More recently, a new point of view has emerged which yields a more direct solution to this problem, without requiring system-theoretic assumptions (Ferrante and Ntogramatzidis 2013a,b; Ntogramatzidis and Ferrante 2013).

The discussion here is restricted to the discrete-time case; for the corresponding continuous-time counterpart, we will only make some comments and refer to the literature.

Notation. For the reader's convenience, we briefly review some, mostly standard, matrix notation used throughout the paper. Given a matrix $B \in \mathbb{R}^{n \times m}$, we denote by $B^\top$ its *transpose* and by $B^\dagger$ its *Moore-Penrose pseudo-inverse*, the unique matrix $B^\dagger$ that satisfies $BB^\dagger B = B$, $B^\dagger B B^\dagger = B^\dagger$, $(BB^\dagger)^\top = BB^\dagger$, and $(B^\dagger B)^\top = B^\dagger B$. The *kernel* of B is the subspace $\{x \in \mathbb{R}^n \mid Bx = 0\}$ and is denoted $\ker B$. The *image* of B is the subspace $\{y \in \mathbb{R}^m \mid \exists x \in \mathbb{R}^n : y = Ax\}$ and is denoted by $\operatorname{im} B$. Given a square matrix A, we denote by $\sigma(A)$ its *spectrum*, i.e., the set of its eigenvalues. We write $A_1 > A_2$ (resp. $A_1 \geq A_2$) when $A_1 - A_2$ is *positive definite* (resp. *positive semidefinite*).

Classical Finite-Horizon Linear-Quadratic Optimal Control

The simplest classical version of the finite-horizon LQ optimal control is Problem 1. By employing some standard linear algebra, this problem may be solved by the classical technique known as "completion of squares": First of all, the cost can be rewritten as

$$J_{N,x_0}(u) = \sum_{t=0}^{N-1} [x_t^\top \ u_t^\top] \Pi \begin{bmatrix} x_t \\ u_t \end{bmatrix}$$

$$+ x_N^\top W x_N, \ \Pi \stackrel{\text{def}}{=} \begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix}$$

$$\stackrel{\text{def}}{=} \begin{bmatrix} C^\top \\ D^\top \end{bmatrix} [C \ D] = \Pi^\top \geq 0. \quad (3)$$

Now, let $X_0, X_1, \ldots, X_N$ be an arbitrary sequence of $n \times n$ symmetric matrices. We have the identity

$$\sum_{t=0}^{N-1} \left[x_{t+1}^\top X_{t+1} x_{t+1} - x_t^\top X_t x_t \right]$$
$$+ x_0^\top X_0 x_0 - x_N^\top X_N x_N = 0. \quad (4)$$

Adding (4)–(3) and using the expression (1) for x_{t+1}, we get

$$J_{N,x_0}(u) = \sum_{t=0}^{N-1} [x_t^\top \ u_t^\top]$$

$$\begin{bmatrix} Q + A^\top X_{t+1} A - X_t & S + A^\top X_{t+1} B \\ S^\top + B^\top X_{t+1} A & R + B^\top X_{t+1} B \end{bmatrix}$$

$$\begin{bmatrix} x_t \\ u_t \end{bmatrix} + x_N^\top (W - X_N) x_N + x_0^\top X_0 x_0, \quad (5)$$

which holds for any sequence of matrices X_t. With $X_N \stackrel{\text{def}}{=} W$ fixed, for $t = N-1, N-2, \ldots, 0$, let

$$X_t \stackrel{\text{def}}{=} Q + A^\top X_{t+1} A - (S + A^\top X_{t+1} B)$$

$$(R + B^\top X_{t+1} B)^\dagger (S^\top + B^\top X_{t+1} A). \quad (6)$$

It is now easy to see that all the matrices of the sequence X_t defined above are positive semidefinite. Indeed, $X_N = W \geq 0$. Assume by induction that $X_{t+1} \geq 0$. Then,

$$M_{t+1} \stackrel{\text{def}}{=} \begin{bmatrix} Q + A^\top X_{t+1} A & S + A^\top X_{t+1} B \\ S^\top + B^\top X_{t+1} A & R + B^\top X_{t+1} B \end{bmatrix}$$

$$= \Pi + \begin{bmatrix} A^\top \\ B^\top \end{bmatrix} X_{t+1} [A \ B] \geq 0.$$

Since X_t is the generalized Schur complement of the right upper block of M_{t+1} in M_{t+1}, it follows that $X_t \geq 0$, which in turns implies

$$R + B^\top X_t B \geq 0. \qquad (10)$$

$$J^* = x_0^\top X_0 x_0. \qquad (10)$$

Moreover, by employing Eq. (6) and recalling that, given a positive semidefinite matrix $\Pi_0 = \begin{bmatrix} Q_0 & S_0 \\ S_0^\top & R_0 \end{bmatrix} = \Pi_0^\top \geq 0$, we have $\begin{bmatrix} S_0 R_0^\dagger S_0^\top & S_0 \\ S_0^\top & R_0 \end{bmatrix} = \begin{bmatrix} S_0 \\ R_0 \end{bmatrix} R_0^\dagger [S_0^\top \ \ R_0] \geq 0$, we easily see that

$$M_{t+1} - \begin{bmatrix} X_t & 0 \\ 0 & 0 \end{bmatrix}$$

$$= \begin{bmatrix} S + A^\top X_{t+1} B \\ R + B^\top X_{t+1} B \end{bmatrix} (R + B^\top X_t B)^\dagger$$

$$\begin{bmatrix} S^\top + A^\top X_{t+1} B & R + B^\top X_{t+1} B \end{bmatrix} \geq 0.$$

Hence, (5) takes the form

$$J_{N,x_0}(u) = \sum_{t=0}^{N-1} \| [(R + B^\top X_{t+1} B)^{1/2}]^\dagger$$

$$(S^\top + B^\top X_{t+1} A) x_t + (R + B^\top X_{t+1} B)^{1/2}$$

$$u_t \|_2^2 + x_0^\top X_0 x_0. \qquad (7)$$

Now it is clear that u_t is optimal if and only if

$$(R + B^\top X_{t+1} B)^{1/2}]^\dagger (S^\top + B^\top X_{t+1} A) x_t$$

$$+ (R + B^\top X_{t+1} B)^{1/2} u_t = 0,$$

whose solutions are parameterized by the feedback control

$$u_t = -K_t x_t + G_t v_t, \qquad (8)$$

where $K_t \stackrel{\text{def}}{=} (R + B^\top X_{t+1} B)^\dagger (S^\top + B^\top X_{t+1} A)$ and $G_t \stackrel{\text{def}}{=} [I - (R + B^\top X_{t+1} B)^\dagger (R + B^\top X_{t+1} B)]$ is the orthogonal projector onto the linear space of vectors that can be added to the optimal control u_t without affecting optimality and v_t is a free parameter. The optimal state trajectory is now given by the closed-loop dynamics

$$x_{t+1} = (A - BK_t) x_t + BG_t v_t. \qquad (9)$$

The optimal cost is clearly

The corresponding results in continuous time can be obtained along the same lines as the discrete-time case; see Ferrante and Ntogramatzidis (2013b) and references therein.

More General Linear-Quadratic Problems

The problem discussed in the previous section presents some limitations that prevent its applicability in several important situations. In particular, three relevant generalizations of the classical problem are:

1. *The fixed endpoint case*, where the states at the endpoints x_0 and x_N are both assigned.
2. *The point-to-point case*, where the initial and terminal values z_0 and z_N of linear combination $z_t = V x_t$ of the state of the dynamical system described by (1) are constrained to be equal to two assigned vectors.
3. *The cyclic case*, where the states at the endpoints x_0 and x_N are not sharply assigned, but they are constrained to be equal (clearly, we can have combinations of (2) and (3)).

All these problems are special cases of a general LQ problem that can be stated as follows:

Problem 2 Consider the dynamical setting (1) of Problem 1. Find a sequence of inputs u_t, with $t = 0, 1, \ldots, N - 1$ and an initial state x_0 minimizing the cost function

$$J_{N,x_0}(u) \stackrel{\text{def}}{=} \sum_{t=0}^{N-1} \| y_t \|^2 + [x_0^\top - \overline{x}_0^\top \ \ x_N^\top - \overline{x}_N^\top]$$

$$\begin{bmatrix} W_{11} & W_{12} \\ W_{12}^\top & W_{22} \end{bmatrix} \begin{bmatrix} x_0 - \overline{x}_0 \\ x_N - \overline{x}_N \end{bmatrix} \qquad (11)$$

under the dynamic constraints (1) and the endpoints constraints

$$V \begin{bmatrix} x_0 \\ x_N \end{bmatrix} = v. \qquad (12)$$

Here $W \stackrel{\text{def}}{=} \begin{bmatrix} W_{11} & W_{12} \\ W_{12}^{\top} & W_{22} \end{bmatrix}$ is a positive semidefinite matrix (partitioned in four blocks) that quadratically penalizes the differences between the initial state x_0 and a desired initial state $\overline{x}_0$ and between the final state x_N and a desired final state $\overline{x}_N$ (This general problem formulation can also encompass problems where the difference $x_0 - x_N$ is not fixed but has to be quadratically penalized with a matrix $\Delta = \Delta^{\top} \geq 0$ in the performance index $J'_{N,x_0}(u) = \sum_{t=0}^{N-1} [x_t^{\top} \ u_t^{\top}] \Pi \begin{bmatrix} x_t \\ u_t \end{bmatrix} + (x_0 - x_N)^{\top} \Delta (x_0 - x_N)$. It is simple to see that this performance index can be brought back to (11) by setting $W = \begin{bmatrix} \Delta & -\Delta \\ -\Delta & \Delta \end{bmatrix}$ and $\overline{x}_0 = \overline{x}_N = 0$.). Equation (12) permits to impose also a hard constraint on an arbitrary linear combination of initial and final states.

The solution of Problem 2 can be obtained by parameterizing the solutions of the so-called extended symplectic system (see Ferrante and Levy (1998) and references therein for a discussion on symplectic matrices and pencils). This solution can be convenient also for the classical case of Problem 1. In fact it does not require to iterate the difference Riccati equation (which can be undesirable if the time horizon is large) but only to solve an algebraic Riccati equation and a related discrete Lyapunov equation.

This solution requires some definitions, preliminary results, and standing assumptions (see Ntogramatzidis and Ferrante (2013) and Ferrante and Ntogramatzidis (2013a) for a more general approach which does not require such assumptions). A detailed proof of the main result can be found in Ferrante and Ntogramatzidis (2007b); see also Zattoni (2008) and Ferrante and Ntogramatzidis (2012). The extended symplectic pencil is defined by

$$zF - G, F \stackrel{\text{def}}{=} \begin{bmatrix} I_n & 0 & 0 \\ 0 & -A^{\top} & 0 \\ 0 & -B^{\top} & 0 \end{bmatrix},$$

$$G \stackrel{\text{def}}{=} \begin{bmatrix} A & 0 & B \\ Q & -I_n & S \\ S^{\top} & 0 & R \end{bmatrix}. \tag{13}$$

where Q, S, R are defined as in (3). We make the following assumptions:

(A1) The pair (A, B) is *modulus controllable*, i.e., $\forall \lambda \in \mathbb{C} \setminus \{0\}$ at least one of the two matrices $[\lambda I - A \mid B]$ and $[\lambda^{-1} I - A \mid B]$ has full row rank.

(A2) The pencil $zF - G$ is regular (i.e., $\det(zF - G)$ is not the zero polynomial) and has no generalized eigenvalues on the unit circle.

Consider the discrete algebraic Riccati equation

$$X = A^{\top} X A - (A^{\top} X B + S)(R + B^{\top} X B)^{-1}$$

$$(S^{\top} + B^{\top} X A) + Q. \tag{14}$$

Under assumptions (A1)–(A2), (14) admits a strongly unmixed solution $X = X^{\top}$, i.e., a solution X for which the corresponding closed-loop matrix

$$A_X \stackrel{\text{def}}{=} A - B K_X, \quad K_X \stackrel{\text{def}}{=} (R + B^{\top} X B)^{-1}$$

$$(S^{\top} + B^{\top} X A) \tag{15}$$

has spectrum that does not contain reciprocal values, i.e., $\lambda \in \sigma(A_X)$ implies $\lambda^{-1} \notin \sigma(A_X)$. It can now be proven that the following closed-loop Lyapunov equation admits a unique solution $Y = Y^{\top} \in \mathbb{R}^{n \times n}$:

$$A_X Y A_X^{\top} - Y + B (R + B^{\top} X B)^{-1} B^{\top} = 0. \tag{16}$$

The following theorem provides an explicit formula parameterizing all the optimal state and control trajectories for Problem 2. Notice that this formula can be readily implemented starting from the problem data.

Theorem 1 *With reference to Problem 2, assume that (A1) and (A2) are satisfied. Let $X = X^{\top}$ be any strongly unmixed solution of (14) and $Y = Y^{\top}$ be the corresponding solution of (16). Let N_V be a basis matrix (In the case when $\ker V = \{0\}$, we consider N_V to be void.) of the null space of V. Moreover, let*

$$F \stackrel{\text{def}}{=} A_X^N,$$

$$K_\star \stackrel{\text{def}}{=} K_X\, Y\, A_X^\top - (R + B^\top X\, B)^{-1} B^\top,$$

$$\hat{X} \stackrel{\text{def}}{=} \operatorname{diag}(-X, X), \quad \overline{x} \stackrel{\text{def}}{=} \begin{bmatrix} \overline{x}_0 \\ \overline{x}_N \end{bmatrix},$$

$$w \stackrel{\text{def}}{=} \begin{bmatrix} v \\ -N_V^\top\, W\, \overline{x} \end{bmatrix}, \quad L \stackrel{\text{def}}{=} \begin{bmatrix} I_n & Y\, F^\top \\ F & Y \end{bmatrix},$$

$$U \stackrel{\text{def}}{=} \begin{bmatrix} 0 & -F^\top \\ 0 & I_n \end{bmatrix},$$

$$M \stackrel{\text{def}}{=} \begin{bmatrix} V\, L \\ N_V^\top\, [\, (\hat{X} - W)\, L - U\,] \end{bmatrix}.$$

Problem 2 *admits solutions if and only if* $w \in im\, M$. *In this case, let* N_M *be a basis matrix of the null space of* M, *and define*

$$\mathcal{P} \stackrel{\text{def}}{=} \{\pi = M^\dagger\, w + N_M\, \zeta \mid \zeta \text{ arbitrary}\}. \quad (17)$$

Then, the set of optimal state and control trajectories of Problem 2 *is parameterized in terms of* $\pi \in \mathcal{P}$, *by*

$$\begin{bmatrix} x(t) \\ u(t) \end{bmatrix} = \begin{cases} \begin{bmatrix} A_X^t & Y\, (A_X^\top)^{N-t} \\ -K_X A_X^t & -K_\star\, (A_X^\top)^{N-t-1} \end{bmatrix} \pi, \\ \qquad\qquad 0 \le t \le N-1, \\ \begin{bmatrix} A_X^N & Y \\ 0 & 0 \end{bmatrix} \pi, \qquad t = N. \end{cases} \quad (18)$$

The interpretation of the above result is the following. As π varies, (18) describes the trajectories of the extended symplectic system. The set $\mathcal{P}$ defined in (17) is the set of π for which these trajectories satisfy the boundary conditions. All the details of this construction can be found in Ferrante and Ntogramatzidis (2007b). If the pair (A, B) is stabilizable, we can choose $X = X^\top$ to be the stabilizing solution of (14). In such case, the matrices A_X^t, $(A_X^\top)^{N-t}$ and $(A_X^\top)^{N-t-1}$ appearing in (18) are asymptotically stable for all $t = 0, \ldots, N$. Thus, in this case, the optimal state trajectory and control are expressed in terms of powers of strictly stable matrices in the overall time interval, thus ensuring the robustness of the obtained solution even for very large time horizons. Indeed, the stabilizing solution of an

algebraic Riccati equation and the solution of a Lyapunov equation may be computed by standard and robust algorithms available in any control package (see the MATLAB® routines `dare.m` and `dlyap.m`). We refer to Ferrante et al. (2005) and Ferrante and Ntogramatzidis (2013b) for the continuous-time counterpart of the above results.

Summary

With the technique discussed in this paper, a large number of LQ problems can be tackled in a unified framework. Moreover, several finite-horizon LQ problems that can be interesting and useful in practice can be recovered as particular cases of the control problem considered here. The generality of the optimal control problem herein considered is crucial in the solution of several $H_2 - H_\infty$ optimization problems whose optimal trajectory is composed of a set of arches, each one solving a parametric LQ subproblem in a specific time horizon and all joined together at the endpoints of each subinterval. In these cases, in fact, a very general form of constraint on the extreme states is essential in order to express the condition of conjunction of each pair of subsequent arches at the endpoints.

Graphs for Modeling Networked Interactions

Mehran Mesbahi[1] and Magnus Egerstedt[2]

[2]Georgia Institute of Technology, Atlanta, GA, USA

Abstract

Graphs constitute natural models for networks of interacting agents. This chapter introduces graph theoretic formalisms that facilitate analysis and synthesis of coordinated control algorithms over networks.

Keywords

Distributed control; Graph theory; Multi-agent networks

Introduction

Distributed and networked systems are characterized by a set of dynamical units (agents, actors, nodes) that share information with each other in order to achieve a global performance objective using locally available information. Information can typically be shared if agents are within communication or sensing range of each other. It is useful to abstract away the particulars of the underlying information-exchange mechanism and simply say that an information link exists between two nodes if they can share information. Such an abstraction is naturally represented in terms of a graph.

A graph is a combinatorial object defined by two constructs: vertices (or nodes) and edges (or links) connecting pairs of distinct vertices. The set of N vertices specified by $V = \{v_1, \ldots, v_N\}$ corresponds to the agents, and an edge between vertices v_i and v_j is represented by (v_i, v_j); the set of all edges constitutes the edge set E. The *graph* G is thus the pair $G = (V, E)$ and the interpretation is that an edge $(v_i, v_j) \in E$

Graphs for Modeling Networked Interactions, Fig. 1 A network of agents equipped with omnidirectional range sensors can be viewed as a graph (undirected in this case), with nodes corresponding to the agents and edges to their pairwise interactions, which are enabled whenever the agents are within a certain distance from each other
if information can flow from vertex i to vertex j. If the information exchange is sensor based, and if there is a state x_i associated with vertex i, e.g., its position, then this information is typically relative, i.e., the states are measured relative to each other and the information obtained along the edge is $x_j - x_i$. If on the other hand the information is communicated, then the full state information x_i can be transmitted along the edge (v_i, v_j). The graph abstraction for a network of agents with sensor-based information exchange is illustrated in Fig. 1.

It is often useful to differentiate between scenarios where the Information exchange is bidirectional – if agent i can get information from agent j, then agent j can get information from agent i – and when it is not. In the language of graph theory, an undirected graph is one where $(v_i, v_j) \in E$ implies that $(v_j, v_i) \in E$, while a directed graph is one where such an implication may not hold.

Graph-Based Coordination Models

Graphs provide structural insights into how different coordination algorithms behave over a network. A coordination algorithm, or protocol, is an update rule that describes how the node states should evolve over time. To understand such protocols, one needs to connect the interaction dynamics to the underlying graph structure. This connection is facilitated through the common intersection of linear system theory and graph theory, namely, the broad discipline of *algebraic graph theory,* by first associating matrices with graphs. For undirected graphs, the following matrices play a key role:

Degree matrix : $\Delta = \text{Diag}\, (\deg(v_1), \ldots, \deg(v_N))$,

 Adjacency matrix : $A = [a_{ij}]$,

where **Diag** denotes a diagonal matrix whose diagonal consists of its argument and $\deg(v_i)$ is the degree of vertex i in the graph, i.e., the cardinality of the set of edges incident on vertex i. Moreover,

$$a_{ij} = \begin{cases} 1 & \text{if}\,(v_j, v_i) \in E \\ 0 & \text{otherwise.} \end{cases}$$

As an example of how these matrices come into play, the so-called *consensus* protocol over scalar states can be compactly written on ensemble form as

$$\dot{x} = -Lx,$$

where $x = [x_1, \ldots, x_N]^T$ and L is the *graph Laplacian:*

$$L = \Delta - A.$$

A useful matrix for directed networks is the incidence matrix, obtained by associating an index to each edge in E. We say that $v_i = \text{tail}(e_j)$ if edge e_j starts at node v_i and $v_i = \text{head}(e_j)$ if e_j ends up at v_i, leading to the

 Incidence matrix : $D = [\iota_{ij}]$,

where

$$
\iota_{ij} = \begin{cases} 1 & \text{if } v_i = \text{head}(e_j) \\ -1 & \text{if } v_i = \text{tail}(e_j) \\ 0 & \text{otherwise.} \end{cases}
$$

It now follows that for undirected networks, the Laplacian has an equivalent representation as

$$
L = DD^T,
$$

where D is the incidence matrix associated with an arbitrary orientation (assignment of directions to the edges) of the undirected graph. This in turn implies that for undirected networks, L is a positive semi-definite matrix and that all of its eigenvalues are nonnegative.

If the network is directed, one has to pay attention to the direction in which information is flowing, using the *in-degree* and *out-degree* of the vertices. The out-degree of vertex i is the number of directed edges that originate at i, and similarly the in-degree of node i is the number of directed edges that terminate at node i. A directed graph is *balanced* if the out-degree is equal to the in-degree at every vertex in the graph. And, the graph Laplacian for directed graphs is obtained by only counting information flowing in the correct direction, i.e., if $L = [\ell_{ij}]$, then l_{ii} is the in-degree of vertex i and $l_{ij} = -1$ if $i \neq j$ and $(v_j, v_i) \in E$.

As a final note, for both directed and undirected networks, it is possible to associate weights to the edges, $w : E \to \Upsilon$ where Υ is set of nonnegative reals or more generally a field, in which case the Laplacian's diagonal elements are the sum of the weights of edges incident to node i and the off-diagonal elements are $-w(v_j, v_i)$ when $(v_j, v_i) \in E$.

Applications

Graph-based coordination has been used in a number of application domains, such as multi-agent robotics, mobile sensor and communication networks, formation control, and biological systems. One way in which the consensus protocol

can be generalized is by defining an edge-tension energy $E_{ij}(\|x_i - x_j\|)$ along each edge in the graph, which gives the total energy in the network as

$$
E(x) = \sum_{i=1}^{N} \sum_{j \in N_i} E_{ij}(\|x_i - x_j\|).
$$

If the agents update their states in such a way as to reduce the total energy in the system according to a gradient descent scheme, the update law becomes

$$
\dot{x} = -\frac{\partial E(x)}{\partial x_i} \quad \Rightarrow \quad \dot{E}(x) = -\left\| \frac{\partial E(x)}{\partial x} \right\|_2^2,
$$

which is nonpositive, i.e., the total energy is reduced in the network. For undirected networks, the ensemble version of this protocol assumes the form

$$
\dot{x} = -L_w(x)x,
$$

where the weighted graph Laplacian is

$$
L_w(x) = DW(x)D^T,
$$

with the weight matrix $W(x) = \mathbf{Diag}(w_1(x), \ldots, w_M(x))$. Here M is the total number of edges in the network, and $w_k(x)$ is the weight that corresponds to the kth edge, given an arbitrary ordering of the edges consistent with the incident matrix D.

This energy interpretation allows for the synthesis of coordination laws for multi-agent networks with desirable properties, such as $E_{ij}(\|x_i - x_j\|) = (\|x_i - x_j\| - d_{ij})^2$ for making the agents reach the desired interagent distances d_{ij}, as shown in Fig. 2. Other applications where these types of constructions have been used include collision avoidance and connectivity maintenance.

Summary and Future Directions

A number of issues pertaining to graph-based distributed control remain to be resolved. These include how heterogeneous networks, i.e., networks comprising of agents with different capabilities,
Graphs for Modeling Networked Interactions, Fig. 2 Fifteen mobile robots are forming the letter "G" by executing a weighted version of the consensus protocol. (**a**) Formation control ($t = 0$). (**b**) Formation control ($t = 5$)

can be designed and understood. A variation to this theme is networks of networks, i.e., networks that are loosely coupled together and that must coordinate at a higher level of abstraction. Another key issue concerns how human operators should interact with networked control systems.

Abstract

An optimization-based approach to linear feedback control system design uses the H_2 norm, or energy of the impulse response, to quantify closed-loop performance. In this entry, an overview of state-space methods for solving H_2 optimal control problems via Riccati equations and matrix inequalities is presented in a continuous-time setting. Both regular and singular problems are considered. Connections to so-called LQR and LQG control problems are also described.

Keywords

Feedback control; H_2 control; Linear matrix inequalities; Linear systems; Riccati equations; State-space methods

Introduction

Modern multivariable control theory based on state-space models is able to handle multi-feedback-loop designs, with the added benefit that design methods derived from it are amenable to computer implementation. Indeed, over the last five decades, a number of multivariable analysis and design methods have been developed using the state-space description of systems. Of these design tools, H_2 optimal control problems involve minimizing the H_2 norm of the closed-loop transfer function from exogenous disturbance signals to a pertinent controlled output signals of a given plant by appropriate use of a internally stabilizing feedback controller. It was not until the 1990s that a complete solution to the general H_2 optimal control problem began to emerge. To elaborate on this, let us concentrate our discussion on H_2 optimal control for a continuous-time system Σ expressed in the following state-space form:

$$\dot{x} = Ax + Bu + Ew \tag{1}$$

$$y = C_1 x + D_{11} u + D_1 w \tag{2}$$

$$z = C_2 x + D_2 u + D_{22} w \tag{3}$$

where x is the state variable, u is the control input, w is the exogenous disturbance input, y is the measurement output, and z is the controlled output. The system Σ is typically an augmented or generalized plant model including weighting functions that reflect design requirements. The H_2 optimal control problem is to find an appropriate control law, relating the control input u to the measured output y, such that when it is applied to the given plant in Eqs. (1)–(3), the

resulting closed-loop system is internally stable, and the H_2 norm of the resulting closed-loop transfer matrix from the disturbance input w to the controlled output z, denoted by $T_{zw}(s)$, is minimized. For a stable transfer matrix $T_{zw}(s)$, the H_2 norm is defined as

$$\|T_{zw}\|_2 = \left(\frac{1}{2\pi} \, \text{trace}\left[\int_{-\infty}^{\infty} T_{zw}(j\omega)T_{zw}^{\text{H}}(j\omega)d\omega\right]\right)^{\frac{1}{2}} \tag{4}$$

where T_{zw}^{H} is the conjugate transpose of T_{zw}. Note that the H_2 norm is equal to the energy of the impulse response associated with $T_{zw}(s)$ and this is finite only if the direct feedthrough term of the transfer matrix is zero.

It is standard to make the following assumptions on the problem data: $D_{11} = 0$; $D_{22} = 0$; (A, B) is stabilizable; (A, C_1) is detectable. The last two assumptions are necessary for the existence of an internally stabilizing control law. The first assumption can be made without loss of generality via a constant loop transformation. Finally, either the assumption $D_{22} = 0$ can be achieved by a pre-static feedback law, or the problem does not yield a solution that has finite H_2 closed-loop norm.

There are two main groups into which all H_2 optimal control problems can be divided. The first group, referred to as regular H_2 optimal control problems, consists of those problems for which the given plant satisfies two additional assumptions:

1. The subsystem from the control input to the controlled output, i.e., (A, B, C_2, D_2), has no invariant zeros on the imaginary axis, and its direct feedthrough matrix, D_2, is injective (i.e., it is tall and of full rank).
2. The subsystem from the exogenous disturbance to the measurement output, i.e., (A, E, C_1, D_1), has no invariant zeros on the imaginary axis and its direct feedthrough matrix, D_1, is surjective (i.e., it is fat and of full rank).

Assumption 1 implies that (A, B, C_2, D_2) is left invertible with no infinite zero, and Assumption 2 implies that (A, E, C_1, D_1) is right invertible with no infinite zero. The second, referred to

as singular H_2 optimal control problems, consists of those which are not regular.

Most of the research in the literature was expended on regular problems. Also, most of the available textbooks and review articles, see, for example, Anderson and Moore (1989), Bryson and Ho (1975), Fleming and Rishel (1975), Kailath (1974), Kwakernaak and Sivan (1972), Lewis (1986), and Zhou et al. (1996), to name a few, cover predominantly only a subset of regular problems. The singular H_2 control problem with state feedback was studied in Geerts (1989) and Willems et al. (1986). Using different classes of state- and measurement-feedback control laws, Stoorvogel et al. (1993) studied the general H_2 optimal control problems for the first time. In particular, necessary and sufficient conditions are provided therein for the existence of a solution in the case of state-feedback control, and in the case of measurement-feedback control. Following this, Trentelman and Stoorvogel (1995) explored necessary and sufficient conditions for the existence of an H_2 optimal controller within the context of discrete-time and sampled-data systems. At the same time Chen et al. (1993, 1994a) provided a thorough treatment of the H_2 optimal control problem with state-feedback controllers. This includes a parameterization and construction of the set of all H_2 optimal controllers and the associated sets of H_2 optimal fixed modes and H_2 optimal fixed decoupling zeros. Also, they provided a computationally feasible design algorithm for selecting an H_2 optimal state-feedback controller that places the closed-loop poles at desired locations whenever possible. Furthermore, Chen and Saberi (1993) and Chen et al. (1996) developed the necessary and sufficient conditions for the uniqueness of an H_2 optimal controller. Interested readers are referred to the textbook Saberi et al. (1995) for a detailed treatment of H_2 optimal control problems in their full generality.

Regular Case

Solving regular H_2 optimal control problems is relatively straightforward. In the case that all of

the state variables of the given plant are available for feedback, i.e., $y = x$, and Assumption 1 holds, the corresponding H_2 optimal control problem can be solved in terms of the unique positive semi-definite stabilizing solution $P \geq 0$ of the following algebraic Riccati equation:

$$A^{\mathrm{T}}P + PA + C_2^{\mathrm{T}}C_2 - (PB + C_2^{\mathrm{T}}D_2)(D_2^{\mathrm{T}}D_2)^{-1}$$
$$(D_2^{\mathrm{T}}C_2 + B^{\mathrm{T}}P) = 0 \qquad (5)$$

The H_2 optimal state-feedback law is given by

$$u = Fx = -(D_2^{\mathrm{T}}D_2)^{-1}(D_2^{\mathrm{T}}C_2 + B^{\mathrm{T}}P)\, x \quad (6)$$

and the resulting closed-loop transfer matrix from w to z, $T_{zw}(s)$, has the following property:

$$\|T_{zw}\|_2 = \sqrt{\operatorname{trace}(E^{\mathrm{T}}PE)} \qquad (7)$$

Note that the H_2 optimal state-feedback control law is generally nonunique. A trivial example is the case when $E = 0$, whereby every stabilizing control law is an optimal solution. It is also interesting to note that the closed-loop system comprising the given plant with $y = x$ and the state-feedback control law of Eq. (6) has poles at all the stable invariant zeros and all the mirror images of the unstable invariant zeros of (A, B, C_2, D_2) together with some other fixed locations in the left half complex plane. More detailed results about the optimal fixed modes and fixed decoupling zeros for general H_2 optimal control can be found in Chen et al. (1993).

It can be shown that the well-known linear quadratic regulation (LQR) problem can be reformulated as a regular H_2 optimal control problem. For a given plant

$$\dot{x} = Ax + Bu, \quad x(0) = X_0 \qquad (8)$$

with (A, B) being stabilizable, the LQR problem is to find a control law $u = Fx$ such that the following performance index is minimized:

$$J = \int_0^\infty (x^{\mathrm{T}}Q_\star x + u^{\mathrm{T}}R_\star u)dt, \qquad (9)$$

where $R_\star > 0$ and $Q_\star \geq 0$ with $(A, Q_\star^{\frac{1}{2}})$ being detectable. The LQR problem is equivalent to finding a static state-feedback H_2 optimal control law for the following auxiliary plant Σ_{LQR}:

$$\dot{x} = Ax + Bu + X_0 w \qquad (10)$$

$$y = x \qquad (11)$$

$$z = \begin{pmatrix} 0 \\ Q_\star^{\frac{1}{2}} \end{pmatrix} x + \begin{pmatrix} R_\star^{\frac{1}{2}} \\ 0 \end{pmatrix} u \qquad (12)$$

For the measurement-feedback case with both Assumptions 1 and 2 being satisfied, the corresponding H_2 optimal control problem can be solved by finding a positive semi-definite stabilizing solution $P \geq 0$ for the Riccati equation given in Eq. (5) and a positive semi-definite stabilizing solution $Q \geq 0$ for the following Riccati equation:

$$QA^{\mathrm{T}} + AQ + EE^{\mathrm{T}} - (QC_1^{\mathrm{T}} + ED_1^{\mathrm{T}})(D_1D_1^{\mathrm{T}})^{-1}$$
$$(D_1E^{\mathrm{T}} + C_1Q) = 0 \qquad (13)$$

The H_2 optimal measurement-feedback law is given by

$$\dot{v} = (A + BF + KC_1)v - Ky, \quad u = Fx \quad (14)$$

where F is as given in Eq. (6) and

$$K = -(QC_1^{\mathrm{T}} + ED_1^{\mathrm{T}})(D_1D_1^{\mathrm{T}})^{-1} \qquad (15)$$

In fact, such an optimal control law is unique and the resulting closed-loop transfer matrix from w to z, $T_{zw}(s)$, has the following property:

$$\|T_{zw}\|_2 = \{\operatorname{trace}(E^{\mathrm{T}}PE)$$
$$+ \operatorname{trace}\left[\left(A^{\mathrm{T}}P + PA + C_2^{\mathrm{T}}C_2\right)Q\right]\}^{\frac{1}{2}}$$
$$(16)$$

Similarly, consider the standard LQG problem for the following system:

$$\dot{x} = Ax + Bu + G_\star d \qquad (17)$$

$$y = Cx + N_\star n, \quad N_\star > 0 \qquad (18)$$

$$z = \begin{pmatrix} H_\star x \\ R_\star u \end{pmatrix}, \quad R_\star > 0, \quad w = \begin{pmatrix} d \\ n \end{pmatrix} \qquad (19)$$

where x is the state, u is the control, d and n white noises with identity covariance, and y the measurement output. It is assumed that (A, B) is stabilizable and (A, C) is detectable. The control objective is to design an appropriate control law that minimizes the expectation of $|z|^2$. Such an LQG problem can be solved via the H_2 optimal control problem for the following auxiliary system Σ_{LQG} (see Doyle 1983):

$$\dot{x} = Ax + Bu + [\, G_\star \quad 0 \,]w \qquad (20)$$

$$y = Cx + [\, 0 \quad N_\star]w \qquad (21)$$

$$z = \begin{pmatrix} H_\star \\ 0 \end{pmatrix} x + \begin{pmatrix} 0 \\ R_\star \end{pmatrix} u \qquad (22)$$

H_2 optimal control problem for discrete-time systems can be solved in a similar way via the corresponding discrete-time algebraic Riccati equations. It is worth noting that many works can be found in the literature that deal with solutions to discrete-time algebraic Riccati equations related to optimal control problems; see, for example, Kucera (1972), Pappas et al. (1980), and Silverman (1976), to name a few. It is proven in Chen et al. (1994b) that solutions to the discrete- and continuous-time algebraic Riccati equations for optimal control problems can be unified. More specifically, the solution to a discrete-time Riccati equation can be done through solving an equivalent continuous-time one and vice versa.

Singular Case

As in the previous section, only the key procedure in solving the singular H_2-optimization problem for continuous-time systems is addressed. For the singular problem, it is generally not possible to obtain an optimal solution, except for some situations when the given plant satisfies certain geometric constraints; see, e.g., Chen et al. (1993) and Stoorvogel et al. (1993). It is more feasible

to find a suboptimal control law for the singular problem, i.e., to find an appropriate control law such that the H_2 norm of the resulting closed-loop transfer matrix from w to z can be made arbitrarily close to the best possible performance. The procedure given below is to transform the original problem into an H_2 almost disturbance decoupling problem; see Stoorvogel (1992) and Stoorvogel et al. (1993).

Consider the given plant in Eqs. (1)–(3) with Assumption 1 and/or Assumption 2 not satisfied. First, find the largest solution $P \geq 0$ for the following linear matrix inequality

$$F(P) = \begin{pmatrix} A^{\mathsf{T}}P + PA + C_2^{\mathsf{T}}C_2 & PB + C_2^{\mathsf{T}}D_2 \\ B^{\mathsf{T}}P + D_2^{\mathsf{T}}C_2 & D_2^{\mathsf{T}}D_2 \end{pmatrix} \geq 0 \tag{23}$$

and find the largest solution $Q \geq 0$ for

$$G(Q) = \begin{pmatrix} AQ + QA^{\mathsf{T}} + EE^{\mathsf{T}} & QC_1^{\mathsf{T}} + ED_1^{\mathsf{T}} \\ C_1 Q + D_1 E^{\mathsf{T}} & D_1 D_1^{\mathsf{T}} \end{pmatrix} \geq 0 \tag{24}$$

Note that by decomposing the quadruples (A, B, C_2, D_2) and (A, E, C_1, D_1) into various subsystems in accordance with their structural properties, solutions to the above linear matrix inequalities can be obtained by solving a Riccati equation similar to those in Eq. (5) or Eq. (5) for the regular case. In fact, for the regular problem, the largest solution $P \geq 0$ for Eq. (23) and the stabilizing solution $P \geq 0$ for Eq. (5) are identical. Similarly, the largest solution $Q \geq 0$ for Eq. (24) and the stabilizing solution $Q \geq 0$ for Eq. (13) are also the same. Interested readers are referred to Stoorvogel et al. (1993) for more details or to Chen et al. (2004) for a more systematic treatment on the structural decomposition of linear systems and its connection to the solutions of the linear matrix inequalities.

It can be shown that the best achievable H_2 norm of the closed-loop transfer matrix from w to z, i.e., the best possible performance over all internally stabilizing control laws, is given by

$$\gamma_2^\star = \{ \mathrm{trace}(E^{\mathsf{T}}PE)$$
$$+ \mathrm{trace}\left[\left(A^{\mathsf{T}}P + PA + C_2^{\mathsf{T}}C_2 \right) Q \right] \}^{\frac{1}{2}} \tag{25}$$

Next, partition

$$F(P) = \begin{pmatrix} C_{\mathrm{P}}^{\mathrm{T}} \\ D_{\mathrm{P}}^{\mathrm{T}} \end{pmatrix} (C_{\mathrm{P}} \quad D_{\mathrm{P}})$$

$$\text{and } G(Q) = \begin{pmatrix} E_{\mathrm{Q}} \\ D_{\mathrm{Q}} \end{pmatrix} (E_{\mathrm{Q}}^{\mathrm{T}} \quad D_{\mathrm{Q}}^{\mathrm{T}}) \qquad (26)$$

where $[C_{\mathrm{P}} \quad D_{\mathrm{P}}]$ and $[E_{\mathrm{Q}}^{\mathrm{T}} \quad D_{\mathrm{Q}}^{\mathrm{T}}]$ are of maximal rank, and then define an auxiliary system Σ_{PQ}:

$$\dot{x}_{\mathrm{PQ}} = A x_{\mathrm{PQ}} + B u + E_{\mathrm{Q}} w_{\mathrm{PQ}} \qquad (27)$$

$$y = C_1 x_{\mathrm{PQ}} + D_{\mathrm{Q}} w_{\mathrm{PQ}} \qquad (28)$$

$$z_{\mathrm{PQ}} = C_{\mathrm{P}} x_{\mathrm{PQ}} + D_{\mathrm{P}} u \qquad (29)$$

It can be shown that the quadruple $(A, B, C_{\mathrm{P}}, D_{\mathrm{P}})$ is right invertible and has no invariant zeros in the open right-half complex plane, and the quadruple $(A, E_{\mathrm{Q}}, C_1, D_{\mathrm{Q}})$ is left invertible and has no invariant zeros in the open right-half complex plane. It can also be shown that there exists an appropriate control law such that when it is applied to Σ_{PQ}, the resulting closed-loop system is internally stable and the H_2 norm of the closed-loop transfer matrix from w_{PQ} to z_{PQ} can be made arbitrarily small. Equivalently, H_2 almost disturbance decoupling problem for Σ_{PQ} is solvable.

More importantly, it can further be shown that if an appropriate control law solves the H_2 almost disturbance decoupling problem for Σ_{PQ}, then it solves the H_2 suboptimal problem for Σ. As such, the solution to the singular H_2 control problem for Σ can be done by finding a solution to the H_2 almost disturbance decoupling problem for Σ_{PQ}. There are vast results available in the literature dealing with disturbance decoupling problems. More detailed treatments can be found in Saberi et al. (1995).

Conclusion

This entry considers the basic solutions to H_2 optimal control problems for continuous-time systems. Both the regular problem and the general singular problem are presented. Readers interested in more details are referred to Saberi et al. (1995) and the references therein, for the complete treatment of H_2 optimal control problems, and to Chap. 10 of Chen et al. (2004) for the unification and differentiation of H_2 control, H_∞ control, and disturbance decoupling control problems. H_2 optimal control is a mature area and has a long history. Possible future research includes issues on how to effectively utilize the theory in solving real-life problems.

Abstract

The area of robust control, where the performance of a feedback system is designed to be robust to uncertainty in the plant being controlled, has received much attention since the 1980s. System analysis and controller synthesis based on the H-infinity norm has been central to progress in this area. This article outlines how the control law that minimizes the H-infinity norm of the closed-loop system can be derived. Connections to other problems, such as game theory and risk-sensitive control, are discussed and finally appropriate problem formulations to produce "good" controllers using this methodology are outlined.

Keywords

Loop-shaping; Robust control; Robust stability

Introduction

The $\mathcal{H}_\infty$-norm probably first entered the study of robust control with the observations made by Zames (1981) in the considering optimal sensitivity. The so-called $\mathcal{H}_\infty$ methods were subsequently developed and are now routinely available to control engineers. In this entry we consider the $\mathcal{H}_\infty$ methods for control, and for simplicity of exposition, we will restrict our attention to linear, time-invariant, finite dimensional, continuous-time systems. Such systems can be represented by their transfer function matrix, $G(s)$, which will then be a rational function of s. Although the Hardy Space, $\mathcal{H}_\infty$, also includes nonrational functions, a rational $G(s)$ is in $\mathcal{H}_\infty$ if and only if it is proper and all its poles are in the open left half plane, in which case the $\mathcal{H}_\infty$-norm is defined as:

$$\|G(s)\|_\infty = \sup_{\mathrm{Re}\,s>0} \sigma_{\max}(G(s)) = \sup_{-\infty<\omega<\infty} \sigma_{\max}((j\omega))$$

(where $\sigma_{\max}$ denotes the largest singular value). Hence for a single input/single output system with transfer function, $g(s)$, its $\mathcal{H}_\infty$-norm, $\|g(s)\|_\infty$ gives the maximum value of $|g(j\omega)|$ and hence the maximum amplification of sinusoidal signals by a system with this transfer function. In the multi-input/multi-output case a similar result holds regarding the system amplification of a vector of sinusoids. There is now a good collection of graduate level textbooks that cover the area in some detail from a variety of approaches, and these are listed

in the Recommended Reading section and the references in this article are generally to these texts rather than to the original journal papers.

Consider a system with transfer function, $G(s)$, input vector, $u(t) \in \mathcal{L}_2(0,\infty)$ and an output vector, $y(t)$, whose Laplace transforms are given by $\bar{u}(s)$ and $\bar{y}(s)$. Such a system will have a state space realization,

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) + Du(t)$$

giving $G(s) = D + C(sI - A)^{-1}B$, which we also denote

$$G(s) = \left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right],$$

and hence $\bar{y}(s) = G(s)\bar{u}(s)$ if $x(0) = 0$.

There are two main reasons for using the $\mathcal{H}_\infty$-norm. Firstly in representing the system gain for input signals $u(t) \in \mathcal{L}_2(0,\infty)$ or equivalently $\bar{u}(j\omega) \in \mathcal{L}_2(-\infty,\infty)$, with corresponding norm $\|u\|_2^2 = \int_0^\infty u(t)^*u(t)\,dt$ (where x^* denotes the conjugate transpose of the vector x (or a matrix)). With these input and output spaces the induced norm of the system is easily shown to be the $\mathcal{H}_\infty$-norm of $G(s)$, and in particular,

$$\|y\|_2 \leq \|G(s)\|_\infty \|u\|_2$$

Hence in a control context the $\mathcal{H}_\infty$-norm can give a measure of the gain, for example, from disturbances to the resulting errors. In the interconnection of systems, the property that $\|P(s)Q(s)\|_\infty \leq \|P(s))\|_\infty \|Q(s)\|_\infty$ is often useful.

The second reason for using the $\mathcal{H}_\infty$-norm is in representing uncertainty in the plant being controlled, e.g., the nominal plant is $P_o(s)$ but the actual plant is $P(s) = P_o(s) + \Delta(s)$ where $\|\Delta(s)\|_\infty \leq \delta$.

A typical control design problem is given in Fig. 1, i.e.,

$$\begin{bmatrix} \bar{z} \\ \bar{y} \end{bmatrix} = P\begin{bmatrix} \bar{w} \\ \bar{u} \end{bmatrix} = \begin{bmatrix} P_{11}\bar{w} + P_{12}\bar{u} \\ P_{21}\bar{w} + P_{22}\bar{u} \end{bmatrix}$$
$$\bar{u} = K\bar{y}$$
H-Infinity Control, Fig. 1 Lower linear fractional transformation: feedback system

$$\Rightarrow \bar{y} = (I - P_{22}K)^{-1}P_{21}\bar{w},$$
$$\bar{u} = K(I - P_{22}K)^{-1}P_{21}\bar{w}$$
$$\bar{z} = \left(P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21}\right)\bar{w}$$
$$=: \mathcal{F}_l(P,K)\bar{w} =: T_{z\leftarrow w}\bar{w}$$

where $\mathcal{F}_l(P,K)$ denotes the lower Linear Fractional Transformation (LFT) with connection around the lower terminals of P as in Fig. 1.

The standard $\mathcal{H}_\infty$-control synthesis problem is to find a controller with transfer function, K, that

> stabilizes the closed-loop system in Fig. 1 and minimizes $\|\mathcal{F}_l(P,K)\|_\infty$.

That is, the controller is designed to minimize the worst-case effect of the disturbance w on the output/error signal z as measured by the $\mathcal{L}_2$ norm of the signals. This article will describe the solution to this problem.
Robust Stability

Before we describe the solution to the synthesis problem, consider the problem of the robust stability of an uncertain plant with a feedback controller. Suppose the plant is given by the upper LFT, $\mathcal{F}_u(P,\Delta)$ with $\|\Delta\|_\infty \leq 1/\gamma$ as illustrated in Fig. 2,

$$\bar{y} = \mathcal{F}_u(P,\Delta)\bar{u}, \tag{1}$$
H-Infinity Control, Fig. 2 Upper linear fractional transformation

H-Infinity Control, Fig. 3 Feedback system with plant uncertainty

where $\mathcal{F}_u(P,K) := P_{22} + P_{21}\Delta(I - P_{11}\Delta)^{-1}P_{12}$

$$\text{(2)}$$

The *small gain theorem* then states that the feedback system of Fig. 3 will be stable for all such Δ if the feedback connection of P_{22} and K is stable and $\|\mathcal{F}_l(P,K)\|_\infty < \gamma$. This robust stability result is valid if P and Δ are both stable; more care is required when either or both are unstable but with such care a similar result is true.

Let us consider a couple of examples. First suppose that the uncertainty is represented as output multiplicative uncertainty,

$$P_\Delta = (I + W_1 \Delta W_2) P_o = \mathcal{F}_u\left(\begin{bmatrix} 0 & W_2 P_o \\ W_1 & P_o \end{bmatrix}, \Delta\right)$$

with robust stability test given by

$$\|\mathcal{F}_l\left(\begin{bmatrix} 0 & W_2 P_o \\ W_1 & P_o \end{bmatrix}, K\right)\|_\infty$$
$$= \|W_2 P_o K (I - P_o K)^{-1} W_1\|_\infty < \gamma$$

As a second example consider the plants $P_\Delta = (\tilde{M} + \Delta_M)^{-1}(\tilde{N} + \Delta_N)$, with $\Delta = \begin{bmatrix} \Delta_N & \Delta_M \end{bmatrix}$ and $\|\Delta\|_\infty \leq 1/\gamma$. Here $P_o = \tilde{M}^{-1}\tilde{N}$ is a left coprime factorization of the nominal plant and the plants P_Δ are represented by perturbations to these coprime factors. In this case $P_\Delta = \mathcal{F}_u(P, \Delta)$, where

$$P = \begin{bmatrix} \begin{bmatrix} 0 \\ -\tilde{M}^{-1} \\ \tilde{M}^{-1} \end{bmatrix} & \begin{bmatrix} I \\ -\tilde{M}^{-1}\tilde{N} \\ \tilde{M}^{-1}\tilde{N} \end{bmatrix} \end{bmatrix}$$

and the robust stability test will be

$$\|\mathcal{F}_l(P,K)\|_\infty = \left\|\begin{bmatrix} K \\ -I \end{bmatrix}(I - P_o K)^{-1}\tilde{M}^{-1}\right\|_\infty < \gamma$$

This is related to plant perturbations in the gap metric (see Vinnicombe 2001). It is therefore observed that the robust stability test for these useful representations of uncertain plants is given by an $\mathcal{H}_\infty$-norm test just as in the controller synthesis problem.

Derivation of the $\mathcal{H}_\infty$-Control Law

In this section we present a solution to the $\mathcal{H}_\infty$-control problem and give some interpretations of the solution. The approach presented is as in by Doyle et al. (1989); see also Zhou et al. (1996). We will make some simplifying structural assumptions to make the formulae less complex and will *not* state the required assumptions on rank, stabilizability, and detectability. Let the system in Fig. 1 be described by the equations:

$$\dot{x}(t) = Ax(t) + B_1 w(t) + B_2 u(t) \qquad \text{(3)}$$

$$z(t) = C_1 x(t) + D_{12} u(t) \qquad (4)$$

$$y(t) = C_2 x(t) + D_{21} w(t) \qquad (5)$$

i.e., in Fig. 1

$$P = \left[\begin{array}{c|cc} A & B_1 & B_2 \\ \hline C_1 & 0 & D_{12} \\ C_2 & D_{21} & 0 \end{array} \right]$$

where we also assume, with little loss of generality, that $D_{12}^* D_{12} = I$, $D_{21} D_{21}^* = I$, $D_{12}^* C_1 = 0$ and $B_1 D_{21}^* = 0$. Since we wish to have $\|T_{z \leftarrow w}\|_\infty < \gamma$, we need to find u such that

$$\|z\|_2^2 - \gamma^2 \|w\|_2^2 < 0 \text{ for all } w \neq 0 \in \mathcal{L}_2(0, \infty).$$

We could consider w to be an adversary trying to make this expression positive, while u has to ensure that it always remains negative in spite of the malicious intentions of w, as in a noncooperative game. Suppose that there exists a solution, X_∞, to the Algebraic Riccati Equation (ARE),

$$A^* X_\infty + X_\infty A + C_1^* C_1$$
$$+ X_\infty (\gamma^{-2} B_1 B_1^* - B_2 B_2^*) X_\infty = 0 \quad (6)$$

with $X_\infty \geq 0$ and $A + (\gamma^{-2} B_1 B_1^* - B_2 B_2^*) X_\infty$ a stable "A-matrix." A simple substitution then gives that

$$\frac{d}{dt}(x(t)^* X_\infty x(t)) = -z^* z + \gamma^2 w^* w$$
$$+ v^* v - \gamma^2 r^* r$$

where

$$v := u + B_2^* X_\infty x, \quad r := w - \gamma^{-2} B_1^* X_\infty x.$$

Now let $x(0) = 0$ and assuming stability so that $x(\infty) = 0$, then integrating from 0 to ∞ gives

$$\|z\|_2^2 - \gamma^2 \|w\|_2^2 = \|v\|_2^2 - \gamma^2 \|r\|_2^2 \qquad (7)$$

If the state is available to u, then the control law $u = -B_2^* X_\infty x$ gives $v = 0$ and $\|z\|_2^2 - \gamma^2 \|w\|_2^2 < 0$ for all $w \neq 0$. It can be shown that (6) has a solution if there exists a controller

such that $\|\mathcal{F}_l(P, K)\|_\infty < \gamma$. In addition since transposing a system does not change its $\mathcal{H}_\infty$-norm, the following dual ARE will also have a solution, $Y_\infty \geq 0$,

$$AY_\infty + Y_\infty A^* + B_1 B_1^*$$
$$+ Y_\infty(\gamma^{-2} C_1^* C_1 - C_2^* C_2) Y_\infty = 0 \quad (8)$$

To obtain a solution to the output feedback case, note that (7) implies that $\|z\|_2^2 < \gamma^2 \|w\|_2^2$ if and only if $\|v\|_2^2 < \gamma^2 \|r\|_2^2$ and $\bar{v} = \mathcal{F}_l(P_{\text{tmp}}, K)\bar{r}$ where

$$\begin{bmatrix} \bar{v} \\ \bar{y} \end{bmatrix} = P_{\text{tmp}} \begin{bmatrix} \bar{r} \\ \bar{u} \end{bmatrix},$$

and

$$P_{\text{tmp}} = \left[\begin{array}{c|cc} A + \gamma^{-2} B_1 B_1^* X_\infty & B_1 & B_2 \\ \hline B_2^* X_\infty & 0 & I \\ C_2 & D_{21} & 0 \end{array} \right]$$

The special structure of this problem enables a solution to be derived in much the same way as the dual of the state feedback problem. The corresponding ARE will have a solution $Y_{\text{tmp}} = (I - \gamma^{-2} Y_\infty X_\infty)^{-1} Y_\infty \geq 0$ if and only if the spectral radius $\rho(Y_\infty X_\infty) < \gamma^2$.

The above outline, supported by significant technical detail and assumptions, will therefore demonstrate that there exists a stabilizing controller, $K(s)$, such that the system described by (3–1) satisfies $\|T_{z \leftarrow w}\|_\infty < \gamma$ if and only if there exist stabilizing solutions to the AREs in (6) and (8) such that

$$X_\infty \geq 0, \ \ Y_\infty \geq 0, \ \ \rho(Y_\infty X_\infty) < \gamma^2 \qquad (9)$$

The state equations for the resulting controller can be written as

$$\dot{\hat{x}} = A\hat{x} + B_1 \hat{w}_{\text{worst}} + B_2 u + Z_\infty L_\infty (C_2 \hat{x} - y)$$

$$u = F_\infty \hat{x}, \ \ \hat{w}_{\text{worst}} = \gamma^{-2} B_1^* X_\infty \hat{x}$$

$$F_\infty := -B_2^* X_\infty, \ \ L_\infty := -Y_\infty C_2^*,$$

$$Z_\infty := (I - \gamma^{-2} Y_\infty X_\infty)^{-1}$$

giving feedback from a state estimator in the presence of an estimate of the worst-case disturbance.

As $\gamma \to \infty$ the standard LQG controller is obtained with state feedback of a state estimate obtained from a Kalman filter. In contrast to the LQG problem, the controller depends on the value of γ, and if this is chosen to be too small, then one of the conditions in (9) will be violated. In order to determine the minimum achievable value of γ, a bisection search over γ can be performed checking (9) for each candidate value of γ.

In the limit as $\gamma \to \gamma_{\text{opt}}$ (its minimum value), a variety of situations can arise and the formulae given here may become ill-conditioned. Typically achieving γ_{opt} is more of an interesting and sometimes challenging mathematical exercise rather than a control system requirement.

This control problem does not have a unique solution, and all solutions can be characterized by an LFT form such as $K = \mathcal{F}_l(M, Q)$ where $Q \in \mathcal{H}_\infty$ with $\|Q\|_\infty < 1$, the present solution is sometimes referred to as the "central solution" obtained with $Q = 0$.

Relations for Other Solution Methods and Problem Formulations

The $\mathcal{H}_\infty$-control problem has been shown to be related to an extraordinarily wide variety of mathematical techniques and to other problem areas, and investigations of these connections have been most fruitful. Earlier approaches (see Francis 1988) firstly used the characterization of all stabilizing controllers of Youla et al. (see Vidyasagar 1985) which shows that all stable closed-loop systems can be written as

$$\mathcal{F}_l(P, K) = T_1 + T_2 Q T_3, \text{ where } Q \in \mathcal{H}_\infty$$

and then solved the model matching problem $\inf_{Q \in \mathcal{H}_\infty} \|T_1 + T_2 Q T_3\|_\infty$. This model matching problem is related to interpolation theory and resulted in a productive interaction with the operator theory. One solution method reduces this problem to J-spectral factorisation problems

$\left(\text{where } J = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}\right)$ and generates state-space solutions to these problems (Kimura 1997).

The derivation above clearly demonstrates relations to noncooperative differential games, and this is fully developed in Başar and Bernhard (1995) and Green and Limebeer (1995).

The model matching problem is clearly a convex optimization problem. The solution of linear matrix inequalities can give effective methods for solving certain convex optimization problems (e.g., calculating the $\mathcal{H}_\infty$ norm using the bounded real lemma) and can be exploited in the $\mathcal{H}_\infty$-control problem. See Boyd and Barratt (1991) for a variety of results on convex optimization and control and Dullerud and Paganini (2000) for this approach in robust control.

As noted above there is a family of solutions to the $\mathcal{H}_\infty$-control problem. The central solution in fact minimizes the entropy integral given by

$$I(T_{z \leftarrow w}; \gamma) := -\frac{\gamma^2}{2\pi} \int_{-\infty}^{\infty} \ln$$
$$\left| \det(I - \gamma^{-2} T_{z \leftarrow w}(j\omega)^* T_{z \leftarrow w}(j\omega)) \right| \, d\omega \tag{10}$$

It can be seen that this criterion will penalize the singular values of $T_{z \leftarrow w}(j\omega)$ from being close to γ for a large range of frequencies.

One of the more surprising connections is with the risk-sensitive stochastic control problem (Whittle 1990) where w is assumed to be Gaussian white noise and it is desired to minimize

$$J_T(\gamma) := \frac{\gamma^2}{T} \ln \mathbf{E} \left\{ e^{\frac{1}{2}\gamma^{-2} V_T} \right\} \tag{11}$$

$$\text{where } V_T := \int_{-T}^{T} z(t)^* z(t) \, dt \tag{12}$$

The situation with $\gamma^2 > 0$ corresponds to the risk averse controller since large values of V_T are heavily penalized by the exponential function. It can be shown that if $\|T_{z \leftarrow w}\|_\infty < \gamma$, then

$$\lim_{T \to \infty} J_T(\gamma) = I(T_{z \leftarrow w}; \gamma)$$

and hence the central controller minimizes both the entropy integral and the risk-sensitive cost

function. When γ is chosen to be too small, Whittle refers to the controller having a "neurotic breakdown" because the cost will be infinite for all possible control laws! If in (11) we set $\gamma^2 = -\theta^{-1}$, then the entropy minimizing controller will have $\theta < 0$ and will be risk-averse. The risk neutral controller is when $\theta \to 0$, $\gamma \to \infty$ and gives the standard LQG case. If $\theta > 0$, then the controller will be risk-seeking, believing that large variance will be in its favor.

Controller Design with $\mathcal{H}_\infty$ Optimization

The above solutions to the $\mathcal{H}_\infty$ mathematical problem do not give guidance on how to set up a problem to give a "good" control system design. The problem formulation typically involves identifying frequency-dependent weighting matrices to characterize the disturbances, w, and the relative importance of the errors, z (see Skogestad and Postlethwaite 1996). The choice of weights should also incorporate system uncertainty to obtain a robust controller.

One approach that combines both closed-loop system gain and system uncertainty is called $\mathcal{H}_\infty$ *loop-shaping* where the desired closed-loop behavior is determined by the design of the loop-shape using pre- and post-compensators and the system uncertainty is represented in the gap metric (see Vinnicombe 2001). This makes classical criteria such as low frequency tracking error, bandwidth, and high-frequency roll-off all easily incorporated. In this framework the performance and robustness measures are very well matched to each other. Such an approach has been successfully exploited in a number of practical examples (e.g., Hyde (1995) for flight control taken through to successful flight tests). Standard control design software packages now routinely have $\mathcal{H}_\infty$-control design modules.

Summary and Future Directions

We have outlined the derivation of $\mathcal{H}_\infty$ controllers with straightforward assumptions that

nevertheless exhibit most of the features of linear time-invariant systems without such assumptions and for which routine design software is now available. Connections to a surprisingly large range of other problems are also discussed.

Generalizations to more general cases such as time-varying and nonlinear systems, where the norm is interpreted as the induced norm of the system in $\mathcal{L}_2$, can be derived although the computational aspects are no longer routine. For the problems of robust control, there are necessarily continuing efforts to match the mathematical representation of system uncertainty and system performance to the physical system requirements and to have such representations amenable to analysis and computation.

History of Adaptive Control

Karl Åström
Department of Automatic Control, Lund
University, Lund, Sweden

Abstract

This entry gives an overview of the development of adaptive control, starting with the early efforts in flight and process control. Two popular schemes, the model reference adaptive controller and the self-tuning regulator, are described with a thumbnail overview of theory and applications. There is currently a resurgence in adaptive flight control as well as in other applications. Some reflections on future development are also given.

Keywords

Adaptive control; Auto-tuning; Flight control; History; Model reference adaptive control; Process control; Robustness; Self-tuning regulators; Stability

Introduction

In everyday language, *to adapt* means to change a behavior to conform to new circumstances, for example, when the pupil area changes to accommodate variations in ambient light. The distinction between adaptation and conventional feedback is subtle because feedback also attempts to reduce the effects of disturbances and plant uncertainty. Typical examples are *adaptive optics* and *adaptive machine tool control* which are conventional feedback systems, with controllers having constant parameters. In this entry we take the pragmatic attitude that an adaptive controller is a controller that can modify its *behavior* in response to changes in the dynamics of the process and the character of the disturbances, by adjusting the controller parameters.

Adaptive control has had a colorful history with many ups and downs and intense debates in the research community. It emerged in the 1950s stimulated by attempts to design autopilots for supersonic aircrafts. Autopilots based on constant-gain, linear feedback worked well in one operating condition but not over the whole flight envelope. In process control there was also a need for automatic tuning of simple controllers.

Much research in the 1950s and early 1960s contributed to conceptual understanding of adaptive control. Bellman showed that *dynamic programming* could capture many aspects of adaptation (Bellman 1961). Feldbaum introduced the notion of *dual control*, meaning that control should be probing as well as directing; the controller should thus inject test signals to obtain better information. Tsypkin showed that schemes for *learning and adaptation* could be captured in a common framework (Tsypkin 1971).

Gabor's work on adaptive filtering (Gabor et al. 1959) inspired Widrow to develop an analogue neural network (Adaline) for adaptive control (Widrow 1962). Widrow's adaptation mechanism was inspired by Hebbian learning in biological systems (Hebb 1949).

There are adaptive control problems in economics and operations research. In these fields the problems are often called *decision making under uncertainty*. A simple idea, called the *certainty equivalence principle* proposed by Simon (1956), is to neglect uncertainty and treat estimates as if they are true. Certainty equivalence was commonly used in early work on adaptive control.

A period of intense research and ample funding ended dramatically in 1967 with a crash of the rocket powered X15-3 using Honeywell's MH-96 self-oscillating adaptive controller. The self-oscillating adaptive control system has, however, been successfully used in several missiles.

Research in adaptive control resurged in the 1970s, when the two schemes the model reference adaptive control (MRAC) and the self-tuning regulator (STR) emerged together with successful applications. The research was influenced by stability theory and advances in the field of system identification. There was an intensive period of research from the late 1970s through the 1990s. The insight and understanding of stability, convergence, and robustness increased. Recently there has been renewed interest because of flight control (Hovakimyan and Cao 2010; Lavretsky and Wise 2013) and other applications; there is, for example a need for adaptation in autonomous systems.

The Brave Era

Supersonic flight posed new challenges for flight control. Eager to obtain results, there was a very short path from idea to flight test with very little theoretical analysis in between. A number of research projects were sponsored by the US air force. Adaptive flight control systems were developed by General Electric, Honeywell, MIT, and other groups. The systems are documented in the Self-Adaptive Flight Control Systems Symposium held at the Wright Air Development Center in 1959 (Gregory 1959) and the book (Mishkin and Braun 1961).

Whitaker of the MIT team proposed the model reference adaptive controller system which is based on the idea of specifying the performance of a servo system by a reference. Honeywell proposed a self-oscillating adaptive system (SOAS) which attempted to keep a given gain margin by bringing the system to self-oscillation. The system was flight-tested on several aircrafts. It experienced a disaster in a test on the X-15. Combined with the success of gain scheduling

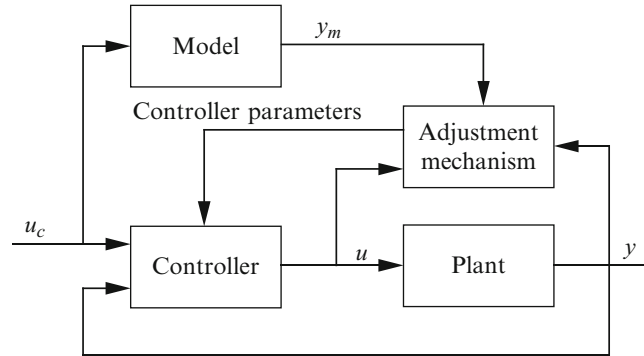
based on air data sensors, the interest in adaptive flight control diminished significantly.

There was also interest of adaptation for process control. Foxboro patented an adaptive process controller with a pneumatic adaptation mechanism in 1950 (Foxboro 1950). DuPont had joint studies with IBM aimed at computerized process control. Kalman worked for a short time at the Engineering Research Laboratory at DuPont, where he started work that led to a paper (Kalman 1958), which is the inspiration of the self-tuning regulator. The abstract of this entry has the statement, *This paper examines the problem of building a machine which adjusts itself automatically to control an arbitrary dynamic process*, which clearly captures the dream of early adaptive control.

Draper and Li investigated the problem of operating aircraft engines optimally, and they developed a self-optimizing controller that would drive the system towards optimal working conditions. The system was successfully flight-tested (Draper and Li 1966) and initiated the field of *extremal control*.

Many of the ideas that emerged in the brave era inspired future research in adaptive control. The MRAC, the STR, and extremal control are typical examples.

Model Reference Adaptive Control (MRAC)

The MRAC was one idea from the early work on flight control that had a significant impact on adaptive control. A block diagram of a system with model reference adaptive control is shown in Fig. 1. The system has an ordinary feedback loop with a controller, having adjustable parameters, and the process. There is also a reference model which gives the ideal response y_m to the command signal y_m and a mechanism for adjusting the controller parameters θ. The parameter adjustment is based on the process output y, the control signal u, and the output y_m of the reference model. Whitaker proposed the following rule for adjusting the parameters:


$$\frac{d\theta}{dt} = -\gamma e\,\frac{\partial e}{\partial \theta}, \tag{1}$$

where $e = y - y_m$ and $\partial e / \partial \theta$ is the sensitivity derivative. Efficient ways to compute the sensitivity derivative were already available in sensitivity theory. The adaptation law (1) became known as the *MIT rule*.

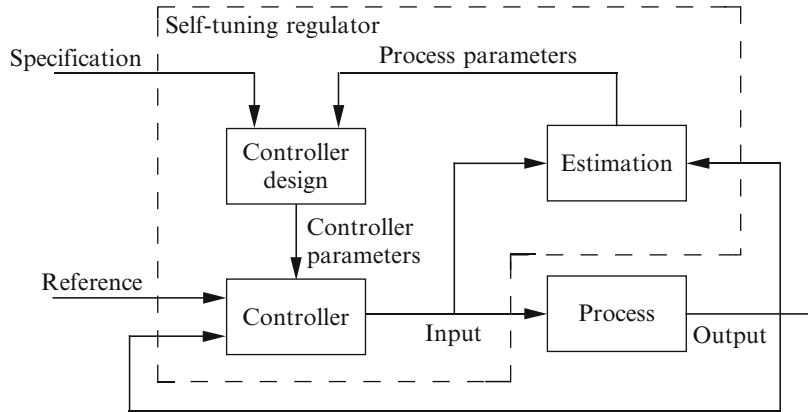
Experiments and simulations of the model reference adaptive systems indicated that there could be problems with instability, in particular if the adaptation gain γ in Eq. (1) is large. This observation inspired much theoretical research. The goal was to replace the MIT rule by other parameter adjustment rules with guaranteed stability; the models used were non linear continuous time differential equations. The papers Butchart and Shackcloth (1965) and Parks (1966) demonstrated that control laws could be obtained using Lyapunov theory. When all state variables are measured, the adaptation laws obtained were similar to the MIT rule (1), but the sensitivity function was replaced by linear combinations of states and control variables. The problem was more difficult for systems that only permitted output feedback. Lyapunov theory could still be used if the process transfer function was strictly positive real, establishing a connection with Popov's hyper-stability theory (Landau 1979). The assumption of a positive real process is a severe restriction because such systems can be successfully controlled by high-gain feedback. The difficulty was finally resolved by using a scheme called *error augmentation* (Monopoli 1974; Morse 1980).

There was much research, and by the late 1980s, there was a relatively complete theory for MRAC and a large body of literature (Anderson et al. 1986; Åström and Wittenmark 1989; Egardt 1979; Goodwin and Sin 1984; Kumar and Varaiya 1986; Narendra and Annaswamy 1989; Sastry and Bodson 1989).The problem of flight control was, however, solved by using gain scheduling based on air data sensors and not by adaptive control (Stein 1980). The MRAC was also extended to nonlinear systems using *back-stepping* (Krstić et al. 1993); Lyapunov stability and passivity were essential ingredients in developing the algorithm and analyzing its stability.

The Self-Tuning Regulator

The self-tuning regulator was inspired by steady-state regulation in process control. The mathematical setting was discrete time stochastic systems. A block diagram of a system with a self-tuning regulator is shown in Fig. 2. The system has an ordinary feedback loop with a controller and the process. There is an external loop for adjusting the controller parameters based on real-time parameter estimation and control design. There are many ways to estimate the process parameters and many ways to do the control design. Simple schemes do not take parameter uncertainty into account when computing the controller parameters invoking *the certainty equivalence principle*.

Single-input, single-output stochastic systems can be modeled by

History of Adaptive Control, Fig. 2 Block diagram of a feedback system with a self-tuning regulator (STR)


$$y(t) + a_1 y(t-h) + \cdots a_n y(t-nh) =$$
$$b_1 u(t-h) + \cdots + b_n u(t-nh) +$$
$$c_1 w(t-h) + \cdots c_n w(t-nh) + e(t), \tag{2}$$

where u is the control signal, y the process output, w a measured disturbance, and e a stochastic disturbance. Furthermore, h is the sampling period and a_k, b_k and c_k, are the parameters. Parameter estimation is typically done using least squares, and a control design that minimized the variance of the variations was well suited for regulation. A surprising result was that if the estimates converge, the limiting controller is a minimum variance controller even if the disturbance e is colored noise (Åström and Wittenmark 1973). Convergence conditions for the self-tuning regulator were given in Goodwin et al. (1980), and a very detailed analysis was presented in Guo and Chen (1991).

The problem of output feedback does not appear for the model (2) because the sequence of past inputs and outputs $y(t-h), \ldots, y(t-nh), u(t-h), \ldots, u(t-nh)$ is indeed a state, albeit not a minimal state representation. The continuous analogue would be to use derivatives of states and inputs which is not feasible because of measurement noise. The selection of the sampling period is however important.

Early industrial experience indicated that the ability of the STR to adapt feedforward gains was particularly useful, because feedforward control requires good models.

Insight from system identification showed that *excitation* is required to obtain good estimates. In the absence of excitation, a phenomenon of *bursting* could be observed. There could be epochs with small control actions due to insufficient excitation. The estimated parameters then drifted towards values close to or beyond the stability boundary generating large control axions. Good parameter estimates were then obtained and the system quickly recovered stability. The behavior then repeated in an irregular fashion. There are two ways to deal with the problem. One possibility is to detect when there is poor excitation and stop adaptation (Hägglund and Åström 2000). The other is to inject perturbations when there is poor excitation in the spirit of dual control.

Robustness and Unification

The model reference adaptive control and the self-tuning regulator originate from different application domains, flight control and process control. The differences are amplified because they are typically presented in different frameworks, continuous time for MRAC and discrete time for the STR. The schemes are, however, not too different. For a given process model and given design criterion the process model can often be re-parameterized in terms of controller parameters, and the STR is then equivalent to an MRAC. Similarly there are indirect MRAC where the process parameters are estimated (Egardt 1979).

A fundamental assumption made in the early analyses of model reference adaptive controllers was that the process model used for analysis had the same structure as the real process. Rohrs at MIT, which showed that systems with guaranteed convergence could be very sensitive to unmodeled dynamics, generated a good deal of research to explore robustness to unmodeled dynamics. Averaging theory, which is based on the observation that there are two loops in an adaptive system, a fast ordinary feedback and a slow parameter adjustment loop, turned out to be a key tool for understanding the behavior of adaptive systems. A large body of theory was generated and many books were written (Ioannou and Sun 1995; Sastry and Bodson 1989).

The theory resulted in several improvements of the adaptive algorithms. In the MIT rule (1) and similar adaptation laws derived from Lyapunov theory, the rate of change of the adaptation rate is a multiplication of the error e with other signals in the system. The adaptation rate may then become very large when signals are large. The analysis of robustness showed that there were advantages in avoiding large adaptation rates by *normalizing* the signals. The stability analysis also required that parameter estimates had to be bounded. To achieve this, parameters were *projected* on regions given by prior parameter bounds. The projection did, however, require prior process knowledge. The improved insight obtained from the robustness analysis is well described in the books Goodwin and Sin (1984), Egardt (1979), Åström and Wittenmark (1989), Narendra and Annaswamy (1989), Sastry and Bodson (1989), Anderson et al. (1986), and Ioannou and Sun (1995).

Applications

There were severe practical difficulties in implementing the early adaptive controllers using the analogue technology available in the brave era. Kalman used a hybrid computer when he attempted to implement his controller. There were dramatic improvements when mini- and microcomputers appeared in the 1970s. Since computers were still slow at the time, it was natural that most experimentats were executed in process control or ship steering which are slow processes. Advances in computing eliminated the technological barriers rapidly.

Self-oscillating adaptive controllers are used in several missiles. In piloted aircrafts there were complaints about the perturbation signals that were always exciting the system.

Self-tuning regulators have been used industrially since the early 1970s. Adaptive autopilots for ship steering were developed at the same time. They outperformed conventional autopilots based on PID control, because disturbances generated by waves were estimated and compensated for. These autopilots are still on the market (Northrop Grumman 2005). Asea (now ABB) developed a small distributed control system, Novatune, which had blocks for self-tuning regulators based on least-squares estimation, and minimum variance control. The company First Control, formed by members of the Novatune team, has delivered SCADA systems with adaptive control since 1985. The controllers are used for high-performance process control systems for pulp mills, paper machines, rolling mills, and pilot plants for chemical process control. The adaptive controllers are based on recursive estimation of a transfer function model and a control law based on pole placement. The controller also admits feedforward. The algorithm is provided with extensive safety logic, parameters are projected, and adaptation is interrupted when variations in measured signals and control signals are too small.

The most common industrial uses of adaptive techniques are automatic tuning of PID controllers. The techniques are used both in single loop controllers and in DCS systems. Many different techniques are used, pattern recognition as well as parameter estimation. The relay autotuning has proven very useful and has been shown to be very robust because it provides proper excitation of the process automatically. Some of the systems use automatic tuning to automatically generate gain schedules, and they also have adaptation of feedback and feedforward gains (Åström and Hägglund 2005).

Summary and Future Directions

Adaptive control has had turbulent history with alternating periods of optimism and pessimism. This history is reflected in the conferences. When the IEEE Conference on Decision and Control started in 1962, it included a Symposium on Adaptive Processes, which was discontinued after the 20th CDC in 1981. There were two IFAC symposia on the Theory of Self-Adaptive Control Systems, the first in Rome in 1962 and the second in Teddington in 1965 (Hammond 1966). The symposia were discontinued but reappeared when the Theory Committee of IFAC created a working group on adaptive control chaired by Prof. Landau in 1981. The group brought the communities of control and signal processing together, and a workshop on Adaptation and Learning in Signal Processing and Control (ALCOSP) was created. The first symposium was held in San Francisco in 1983 and the 11th in Caen in 2013.

Adaptive control can give significant benefits, it can deliver good performance over wide operating ranges, and commissioning of controllers can be simplified. Automatic tuning of PID controllers is now widely used in the process industry. Auto-tuning of more general controller is clearly of interest. Regulation performance is often characterized by the Harris index which compares actual performance with minimum variance control. Evaluation can be dispensed with by applying a self-tuning regulator.

There are adaptive controllers that have been in operation for more than 30 years, for example, in ship steering and rolling mills. There is a variety of products that use scheduling, MRAC, and STR in different ways. Automatic tuning is widely used; virtually all new single loop controllers have some form of automatic tuning. Automatic tuning is also used to build gain schedules semiautomatically. The techniques appear in tuning devices, in single loop controllers, in distributed systems for process control, and in controllers for special applications. There are strong similarities between adaptive filtering and adaptive control. Noise cancellation and adaptive equalization are widely spread uses of adaptation. The signal processing applications are a little easier to analyze because the systems do not have a feedback controller. New adaptive schemes are appearing. The $\mathcal{L}_1$ adaptive controller is one example. It inherits features of both the STR and the MRAC. The *model-free controller* by Fliess and Join (2013) is another example. It is similar to a continuous time version of the self-tuning regulator.

There is renewed interest in adaptive control in the aerospace industry, both for aircrafts and missiles (Lavretsky and Wise 2013). Good results in flight tests have been reported both using MRAC and the recently developed $\mathcal{L}_1$ adaptive controller (Hovakimyan and Cao 2010).

Adaptive control is a rich field, and to understand it well, it is necessary to know a wide range of techniques: nonlinear, stochastic, and sampled data systems, stability, robust control, and system identification.

In the early development of adaptive control, there was a dream of the universal adaptive controller that could be applied to any process with very little prior process knowledge. The insight gained by the robustness analysis shows that knowledge of bounds on the parameters is essential to ensure robustness. With the knowledge available today, adaptive controllers can be designed for particular applications. Design of proper safety nets is an important practical issue. One useful approach is to start with a basic constant-gain controller and provide adaptation as an add-on. This approach also simplifies design of supervision and safety networks.

There are still many unsolved research problems. Methods to determine the achievable adaptation rates are not known. Finding ways to provide proper excitation is another problem. The dual control formulation is very attractive because it automatically generates proper excitation when it is needed. The computations required to solve the Bellman equations are prohibitive, except in very simple cases. The self-oscillating adaptive system, which has been successfully applied to missiles, does provide excitation. The success of the relay auto-tuner for simple controllers indicates that it may be called in to provide excitation of adaptive controllers. Adaptive control can be an important

component of the emerging autonomous system. One may expect that the current upswing in systems biology may provide more inspiration because many biological clearly have adaptive capabilities.

Abstract

The control of systems with hybrid dynamics requires algorithms capable of dealing with the intricate combination of continuous and discrete behavior, which typically emerges from the presence of continuous processes, switching devices, and logic for control. Several analysis and design techniques have been proposed for the control of nonlinear continuous-time plants, but little is known about controlling plants that feature truly hybrid behavior. This short entry focuses on recent advances in the design of feedback control algorithms for hybrid dynamical systems. The focus is on hybrid feedback controllers that are systematically designed employing Lyapunov-based methods. The control design techniques summarized in this entry include control Lyapunov function-based control, passivity-based control, and trajectory tracking control.

Keywords

Feedback control; Hybrid control; Hybrid systems; Asymptotic stability

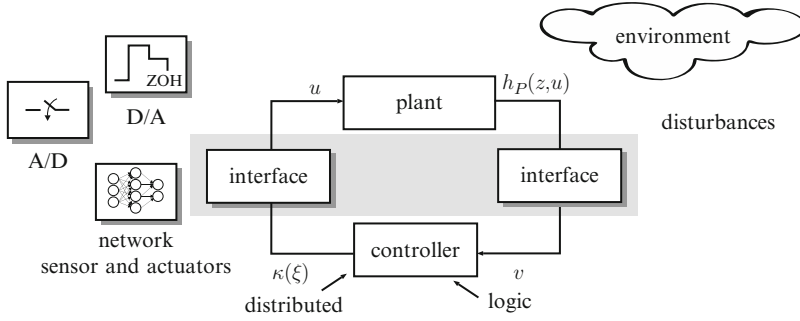
Definition

A *hybrid control system* is a *feedback system* whose variables may flow and, at times, jump. Such a hybrid behavior can be present in one or more of the subsystems of the feedback system: in the system to control, i.e., *the plant*; in the algorithm used for control, i.e., *the controller*; or in the subsystems needed to interconnect the plant and the controller, i.e., *the interfaces/signal conditioners*. Figure 1 depicts a feedback system in closed-loop configuration with such subsystems under the presence of environmental disturbances. Due to its hybrid dynamics, a hybrid control system is a particular type of *hybrid dynamical system*.

Motivation

Hybrid dynamical systems are ubiquitous in science and engineering as they permit capturing the complex and intertwined continuous/discrete behavior of a myriad of systems with variables that flow and jump. The recent popularity of feedback systems combining physical and software components demands tools for stability analysis and control design that can systematically handle such a complex combination. To avoid the issues due to approximating the dynamics of a system, in numerous settings, it is mandatory to keep the system dynamics as pure as possible and to be able to design feedback controllers that can cope with flow and jump behavior in the system.

Modeling Hybrid Dynamical Control Systems

In this entry, hybrid control systems are represented in the framework of *hybrid equations/inclusions* for the study of hybrid dynamical systems. Within this framework, the continuous dynamics of the system are modeled using a differential equation/inclusion, while the discrete dynamics are captured by a difference equation/inclusion. A solution to such a system can *flow* over nontrivial intervals of time and *jump* at certain time instants. The conditions determining whether a solution to a hybrid system should flow or jump are captured by subsets of the state space and input space of the hybrid control system. In this way, a *plant* with hybrid dynamics can be modeled by the hybrid inclusion.


Hybrid Dynamical Systems, Feedback Control of, Fig. 1 A hybrid control system: a feedback system with a plant, controller, and interfaces/signal conditioners

(along with environmental disturbances) as subsystems featuring variables that flow and, at times, jump

$$E \cap ([0, T] \times \{0, 1, \dots J\})$$

can be written in the form

$$\bigcup_{j=0}^{J-1} \left([t_j, t_{j+1}], j \right)$$

for some finite sequence of times $0 = t_0 \leq t_1 \leq t_2 \leq \dots \leq t_J$. A hybrid arc ϕ is a function on a hybrid time domain. The set $E \cap ([0, T] \times \{0, 1, \dots, J\})$ defines a compact hybrid time domain since it is bounded and closed. The hybrid time domain of ϕ is denoted by $\mathrm{dom}\,\phi$. A hybrid arc is such that, for each $j \in \mathbb{N}$, $t \mapsto \phi(t, j)$ is absolutely continuous on intervals of flow $I^j := \{t : (t, j) \in \mathrm{dom}\,\phi\}$ with nonzero Lebesgue measure. A hybrid input u is a function on a hybrid time domain that, for each $j \in \mathbb{N}$, $t \mapsto u(t, j)$ is Lebesgue measurable and locally essentially bounded on the interval I^j.

In this way, a solution to the plant $\mathcal{H}_P$ is given by a pair (ϕ, u) with $\mathrm{dom}\,\phi = \mathrm{dom}\,u$ ($= \mathrm{dom}(\phi, u)$) satisfying

(S0) $(\phi(0,0), u(0,0)) \in \overline{C}_P$ *or* $(\phi(0,0), u(0,0)) \in D_P$, *and* $\mathrm{dom}\,\phi = \mathrm{dom}\,u$;

(S1) For each $j \in \mathbb{N}$ such that I^j has nonempty interior $\mathrm{int}(I^j)$*, we have*

$$(\phi(t, j), u(t, j)) \in C_P \quad \text{for all } t \in \mathrm{int}(I^j)$$

and

$$\frac{d}{dt}\phi(t, j) \in F_P(\phi(t, j), u(t, j))$$
$$\text{for almost all } t \in I^j$$

$$\mathcal{H}_P : \begin{cases} \dot{z} \in F_P(z, u) & (z, u) \in C_P \\ z^+ \in G_P(z, u) & (z, u) \in D_P \\ y = h_P(z, u) \end{cases} \quad (1)$$

where z is the *state* of the plant and takes values from the Euclidean space $\mathbb{R}^{n_P}$, u is the *input* and takes values from $\mathbb{R}^{m_P}$, y is the *output* and takes values from the output space $\mathbb{R}^{r_P}$, and $(C_P, F_P, D_P, G_P, h_P)$ is the *data* of the hybrid system. The set C_P is the *flow set*, the set-valued map F_P is the *flow map*, the set D_P is the *jump set*, the set-valued map G_P is the *jump map*, and the single-valued map h_P is the *output map*. (This hybrid inclusion captures the dynamics of (constrained or unconstrained) continuous-time systems when $D_P = \emptyset$ and G_P is arbitrary. Similarly, it captures the dynamics of (constrained or unconstrained) discrete-time systems when $C_P = \emptyset$ and F_P is arbitrary. Note that while the output inclusion does not explicitly include a constraint on (z, u), the output map is only evaluated along solutions.)

Given an input u, a *solution to a hybrid inclusion* is defined by a state trajectory ϕ that satisfies the inclusions. Both the input and the state trajectory are functions of $(t, j) \in \mathbb{R}_{\geq 0} \times \mathbb{N} := [0, \infty) \times \{0, 1, 2, \dots\}$, where t keeps track of the amount of flow, while j counts the number of jumps of the solution. These functions are given by *hybrid arcs* and *hybrid inputs*, which are defined on *hybrid time domains*. More precisely, hybrid time domains are subsets E of $\mathbb{R}_{\geq 0} \times \mathbb{N}$ that, for each $(T, J) \in E$,

(S2) For each $(t, j) \in \text{dom}(\phi, u)$ *such that* $(t, j + 1) \in \text{dom}(\phi, u)$, *we have*

$$(\phi(t, j), u(t, j)) \in D_P$$

and

$$\phi(t, j + 1) \in G_P(\phi(t, j), u(t, j))$$

A solution pair (ϕ, u) to $\mathcal{H}$ is said to be *complete* if $\text{dom}(\phi, u)$ is unbounded and *maximal* if there does not exist another pair $(\phi, u)'$ such that (ϕ, u) is a truncation of $(\phi, u)'$ to some proper subset of $\text{dom}(\phi, u)'$. A solution pair (ϕ, u) to $\mathcal{H}$ is said to be *Zeno* if it is complete and the projection of $\text{dom}(\phi, u)$ onto $\mathbb{R}_{\geq 0}$ is bounded.

Input and output modeling remark: At times, it is convenient to define inputs $u_c \in \mathbb{R}^{m_{P,c}}$ and $u_d \in \mathbb{R}^{m_{P,d}}$ collecting every component of the input u that affect flows and that affect jumps, respectively (Some of the components of u can be used to define both u_c and u_d, that is, there could be inputs that affect both flows and jumps.). Similarly, one can define y_c and y_d as the components of y that are measured during flows and jumps, respectively.

To control the hybrid plant $\mathcal{H}_P$ in (1), control algorithms that can cope with the nonlinearities introduced by the flow and jump equations/inclusions are required. In general, feedback controllers designed using classical techniques from the continuous-time and discrete-time domain fall short. Due to this limitation, hybrid feedback controllers would be more suitable for the control of plants with hybrid dynamics. Then, following the hybrid plant model above, hybrid controllers for the plant $\mathcal{H}_P$ in (1) will be given by the hybrid inclusion

$$\mathcal{H}_K \ : \ \begin{cases} \dot{\xi} \ \in \ F_K(\xi, v) & (\xi, v) \in C_K \\ \xi^+ \in \ G_K(\xi, v) & (\xi, v) \in D_K \\ \eta \ = \ \kappa(\xi, v) \end{cases} \quad (2)$$

where ξ is the *state* of the controller and takes values from the Euclidean space $\mathbb{R}^{n_K}$, v is the *input* and takes values from $\mathbb{R}^{r_P}$, η is the *output* and takes values from the output space $\mathbb{R}^{m_P}$, and

$(C_K, F_K, D_K, G_K, \kappa)$ is the *data* of the hybrid inclusion defining the hybrid controller.

The control of $\mathcal{H}_P$ via $\mathcal{H}_K$ defines an interconnection through the input/output assignment $u = \eta$ and $v = y$; the system in Fig. 1 without interfaces represents this interconnection. The resulting closed-loop system is a hybrid dynamical system given in terms of a hybrid inclusion/equation with state $x = (z, \xi)$. We will denote such a closed-loop system by $\mathcal{H}$. Its data can be constructed from the data $(C_P, F_P, D_P, G_P, h_P)$ and $(C_K, F_K, D_K, G_K, \kappa)$ of each of the subsystems. Solutions to both $\mathcal{H}_K$ and $\mathcal{H}$ are understood following the notion introduced above.

Definitions and Notions

For convenience, we use the equivalent notation $[x^\top \ y^\top]^\top$ and (x, y) for vectors x and y. Also, we denote by $\mathcal{K}_\infty$ the class of functions from $\mathbb{R}_{\geq 0}$ to $\mathbb{R}_{\geq 0}$ that are continuous, zero at zero, strictly increasing, and unbounded.

The dynamics of hybrid inclusions have right-hand sides given by set-valued maps. Unlike functions or single-valued maps, set-valued maps may return a set when evaluated at a point. For instance, at points in C_P, the set-valued flow map F_P of the hybrid plant $\mathcal{H}_P$ might return more than one value, allowing for different values of the derivative of z. A particular continuity property of set-valued maps that will be needed later is lower semicontinuity. A set-valued map S from $\mathbb{R}^n$ to $\mathbb{R}^m$ is lower semicontinuous if for each $x \in \mathbb{R}^n$ one has that $\liminf_{x_i \to x} S(x_i) \supset S(x)$, where $\liminf_{x_i \to x} S(x_i) = \{z \ : \ \forall x_i \to x, \exists z_i \to z$ s.t. $z_i \in S(x_i) \}$ is the so-called *inner limit* of S.

A vast majority of control problems consist of designing a feedback algorithm that assures that a function of the solutions to the plant approach a desired set-point condition (*attractivity*) and, when close to it, the solutions remain nearby (*stability*). In some scenarios, the desired set-point condition is not necessarily an isolated point, but rather a set. The problem of designing a hybrid controller $\mathcal{H}_K$ for a hybrid plant $\mathcal{H}_P$ typically pertains to the stabilization of sets, in

particular, due to the hybrid controller's state including timers that persistently evolve within a bounded time interval and logic variables that take values from discrete sets. Denoting by $\mathcal{A}$ the set of points to stabilize for the closed-loop system $\mathcal{H}$ and $|\cdot|_{\mathcal{A}}$ as the distance to such set, the following property captures the typically desired properties outlined above. A closed set $\mathcal{A}$ is said to be:

(S) *Stable*: for each $\varepsilon > 0$ there exists $\delta > 0$ such that each maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_{\circ}$, $|x_{\circ}|_{\mathcal{A}} \leq \delta$ satisfies $|\phi(t, j)|_{\mathcal{A}} \leq \varepsilon$ for all $(t, j) \in \mathrm{dom}\,\phi$.

(A) *Attractive*: there exists $\mu > 0$ such that every maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_{\circ}$, $|x_{\circ}|_{\mathcal{A}} \leq \mu$ is bounded and if it is complete satisfies $\lim_{(t, j) \in \mathrm{dom}\,\phi,\ t+j \to \infty} |\phi(t, j)|_{\mathcal{A}} = 0$.

(AS) *Asymptotically stable*: it is stable and attractive.

The basin of attraction of an asymptotically stable set $\mathcal{A}$ is the set of points from where the attractivity property holds. The set $\mathcal{A}$ is said to be globally asymptotically stable when the basin of attraction is equal to the entire state space.

A dynamical system with assigned inputs is said to be detectable when its output being held to zero implies that its state converges to the origin. A similar property can be defined for hybrid dynamical systems. For the closed-loop system $\mathcal{H}$, given sets $\mathcal{A}$ and K, the distance to $\mathcal{A}$ is 0-input detectable relative to K for $\mathcal{H}$ if every complete solution ϕ to $\mathcal{H}$

$$\phi(t, j) \in K \qquad \forall (t, j) \in \mathrm{dom}\,\phi \qquad \Rightarrow$$

$$\lim_{(t, j) \in \mathrm{dom}\,\phi,\ t+j \to \infty} |\phi(t, j)|_{\mathcal{A}} = 0$$

where "$\phi(t, j) \in K$" captures the "output being held to zero" property in the usual detectability notion.

Feedback Control Design for Hybrid Dynamical Systems

Several methods for the design of a hybrid controller $\mathcal{H}_K$ rendering a given set asymptotically stable are given below. At the core of these methods are sufficient conditions in terms of Lyapunov functions guaranteeing that the asymptotic stability property defined in section "Definitions and Notions" holds. Some of the methods presented below exploit such sufficient conditions when applied to the closed-loop system $\mathcal{H}$, while others exploit the properties of the hybrid plant to design controllers with a particular structure. The design methods are presented in order of complexity of the controller, namely, from it being a static state-feedback law to being a generic algorithm with true hybrid dynamics.

CLF-Based Control Design

In simple terms, a control Lyapunov function (CLF) is a regular enough scalar function that decreases along solutions to the system for some values of the unassigned input. When such a function exists, it is very tempting to exploit its properties to construct an asymptotically stabilizing control law. Following the ideas from the literature of continuous-time and discrete-time nonlinear systems, we define control Lyapunov functions for hybrid plants $\mathcal{H}_P$ and present results on CLF-based control design. For simplicity, as mentioned in the *input and output modeling remark* in section "Definitions and Notions," we use inputs u_c and u_d instead u. Also, we restrict the discussion to sets $\mathcal{A}$ that are compact as well as hybrid plants with F_P, G_P single valued and such that $h_P(z, u) = z$. For notational convenience, we use Π to denote the "projection" of C_P and D_P onto $\mathbb{R}^{n_P}$, i.e., $\Pi(C_P) = \{z : \exists u_c \text{ s.t. } (z, u_c) \in C_P\}$ and $\Pi(D_P) = \{z : \exists u_d \text{ s.t. } (z, u_d) \in D_P\}$, and the set-valued maps $\Psi_c(z) = \{u_c : (z, u_c) \in C_P\}$ and $\Psi_d(z) = \{u_d : (z, u_d) \in D_P\}$.

Given a compact set $\mathcal{A}$, a continuously differentiable function $V : \mathbb{R}^{n_P} \to \mathbb{R}$ is a *control Lyapunov function for $\mathcal{H}_P$ with respect to $\mathcal{A}$* if there exist $\alpha_1, \alpha_2 \in \mathcal{K}_{\infty}$ and a continuous, positive definite function ρ such that

$$\alpha_1\,(|z|_{\mathcal{A}}) \leq V(z) \leq \alpha_2(|z|_{\mathcal{A}})$$
$$\forall z \in \mathbb{R}^{n_P}$$
$$\inf_{u_c \in \Psi_c(z)} \langle \nabla V(z), F_P(z, u_c) \rangle \leq -\rho(|z|_{\mathcal{A}})$$

$$\forall z \in \Pi(C_P) \qquad (3)$$

$$\inf_{u_d \in \Psi_d(z)} V(G_P(z, u_d)) - V(z) \leq -\rho(|z|_{\mathcal{A}})$$

$$\forall z \in \Pi(D_P) \qquad (4)$$

With the availability of a CLF, the set $\mathcal{A}$ can be asymptotically stabilized if it is possible to synthesize a controller $\mathcal{H}_K$ from inequalities (3) and (4). Such a synthesis is feasible, in particular, forthe special case of $\mathcal{H}_K$ being a

static state-feedback law $z \mapsto \kappa(z)$. Sufficient conditions guaranteeing the existence of such a controller as well as a particular state-feedback law with point-wise minimum norm are given next.

Given a compact set $\mathcal{A}$ and a control Lyapunov function V (with respect to $\mathcal{A}$), define, for each $r \geq 0$, the set $\mathcal{I}(r) := \{z \in \mathbb{R}^{n_P} : V(z) \geq r\}$. Moreover, for each (z, u_c) and $r \geq 0$, define the function

$$\Gamma_c(z, u_c, r) := \begin{cases} \langle \nabla V(z), F_P(z, u_c) \rangle + \frac{1}{2}\rho(|z|_{\mathcal{A}}) & \text{if } (z, u_c) \in C_P \cap (\mathcal{I}(r) \times \mathbb{R}^{m_{P,c}}), \\ -\infty & \text{otherwise} \end{cases}$$

and, for each (z, u_d) and $r \geq 0$, the function

$$\Gamma_d(z, u_d, r) := \begin{cases} V(G_P(z, u_d)) - V(z) + \frac{1}{2}\rho(|z|_{\mathcal{A}}) & \text{if } (z, u_d) \in D_P \cap (\mathcal{I}(r) \times \mathbb{R}^{m_{P,d}}), \\ -\infty & \text{otherwise} \end{cases}$$

The following result states conditions on the data of $\mathcal{H}_P$ guaranteeing that, for each $r > 0$, there exists a continuous state-feedback law $z \mapsto \kappa(z) = (\kappa_c(z), \kappa_d(z))$ rendering the compact set

$$\mathcal{A}_r := \{z \in \mathbb{R}^{n_P} : V(z) \leq r\}$$

asymptotically stable. This property corresponds to a practical version of asymptotic stabilizability.

Theorem 1 *Given a hybrid plant $\mathcal{H}_P = (C_P, F_P, D_P, G_P, h_P)$, a compact set $\mathcal{A}$, and a control Lyapunov function V for $\mathcal{H}_P$ with respect to $\mathcal{A}$, if*
(C1) C_P and D_P are closed sets, and F_P and G_P are continuous;
(C2) The set-valued maps $\Psi_c(z) = \{u_c : (z, u_c) \in C_P\}$ and $\Psi_d(z) = \{u_d : (z, u_d) \in D_P\}$ are lower semicontinuous with convex values;
(C3) For every $r > 0$, we have that, for every $z \in \Pi(C_P) \cap \mathcal{I}(r)$, the function $u_c \mapsto \Gamma_c(z, u_c, r)$ is convex on $\Psi_c(z)$ and that, for every $z \in \Pi(D_P) \cap \mathcal{I}(r)$, the function $u_d \mapsto \Gamma_c(z, u_d, r)$ is convex on $\Psi_d(z)$;
then, for every $r > 0$, the compact set $\mathcal{A}_r$ is asymptotically stabilizable for $\mathcal{H}_P$ by a state-

feedback law $z \mapsto \kappa(z) = (\kappa_c(z), \kappa_d(z))$ with κ_c continuous on $\Pi(C_P) \cap \mathcal{I}(r)$ and κ_d continuous on $\Pi(D_P) \cap \mathcal{I}(r)$.

Theorem 1 assures the existence of a continuous state-feedback law practically asymptotically stabilizing $\mathcal{A}$. However, Theorem 1 does not provide an expression of an asymptotically stabilizing control law. The following result provides an explicit construction of such a control law.

Theorem 2 *Given a hybrid plant $\mathcal{H}_P = (C_P, F_P, D_P, G_P, h_P)$, a compact set $\mathcal{A}$, and a control Lyapunov function V for $\mathcal{H}_P$ with respect to $\mathcal{A}$, if (C1)–(C3) in Theorem 1 hold then, for every $r > 0$, the state-feedback law pair*

$$\kappa_c : \Pi(C_P) \to \mathbb{R}^{m_{P,c}}, \quad \kappa_d : \Pi(D_P) \to \mathbb{R}^{m_{P,d}}$$

defined on $\Pi(C_P)$ and $\Pi(D_P)$ as

$$\kappa_c(z) := \arg\min\{|u_c| : u_c \in \mathcal{T}_c(z)\}$$

$$\forall z \in \Pi(C_P) \cap \mathcal{I}(r)$$

$$\kappa_d(z) := \arg\min\{|u_d| : u_d \in \mathcal{T}_d(z)\}$$

$$\forall z \in \Pi(D_P) \cap \mathcal{I}(r)$$

respectively, renders the compact set $\mathcal{A}_r$ asymptotically stable for $\mathcal{H}_P$, where $\mathcal{T}_c(z) = \Psi_c(z) \cap \{u_c : \Gamma_c(z, u_c, V(z)) \leq 0\}$ and $\mathcal{T}_d(z) = \Psi_d(z) \cap \{u_d : \Gamma_d(z, u_d, V(z)) \leq 0\}$. Furthermore, if the set-valued maps Ψ_c and Ψ_d have a closed graph, then κ_c and κ_d are continuous on $\Pi(C_P) \cap \mathcal{I}(r)$ and $\Pi(D_P) \cap \mathcal{I}(r)$, respectively.

The stability properties guaranteed by Theorems 1 and 2 are practical. Under further properties, similar results hold when the input u is not partitioned into u_c and u_d. To achieve asymptotic stability (or stabilizability) of $\mathcal{A}$ with a continuous state-feedback law, extra conditions are required to hold nearby the compact set, which for the case of stabilization of continuous-time systems are the so-called *small control properties*. Furthermore, the continuity of the feedback law assures that the closed-loop system has closed flow and jump sets as well as continuous flow and jump maps, which, in turn, due to the compactness of $\mathcal{A}$, implies that the asymptotic stability property is robust. Robustness follows from results for hybrid systems without inputs.

Passivity-Based Control Design

Dissipativity and its special case, passivity, provide a useful physical interpretation of a feedback control system as they characterize the exchange of energy between the plant and its controller. For an open system, passivity (in its very pure form) is the property that the energy stored in the system is no larger than the energy it has absorbed over a period of time. The energy stored in a system is given by the difference between the initial and final energy over a period of time, where the energy function is typically called the *storage function*. Hence, conveniently, passivity can be expressed in terms of the derivative of a storage function (i.e., the rate of change of the internal energy) and the product between inputs and outputs (i.e., the system's power flow). Under further observability conditions, this power inequality can be employed as a design tool by selecting a control law that makes the rate of change of the internal energy negative. This method is called *passivity-based control design*.

The passivity-based control design method can be employed in the design of a controller for

a "passive" hybrid plant $\mathcal{H}_P$, in which energy might be dissipated during flows, jumps, or both. Passivity notions and a passivity-based control design method for hybrid plants are given next. Since the form of the plant's output plays a key role in asserting a passivity property, and this property may not necessarily hold both during flows and jumps, as mentioned in the *input and output modeling remark* in section "Definitions and Notions," we define outputs y_c and y_d, which, for simplicity, are assumed to be single valued: $y_c = h_c(x)$ and $y_d = h_d(x)$. Moreover, we consider the case when the dimension of the space of the inputs u_c and u_d coincides with that of the outputs y_c and y_d, respectively, i.e., a "duality" of the output and input space.

Given a compact set $\mathcal{A}$ and functions h_c, h_d such that $h_c(\mathcal{A}) = h_d(\mathcal{A}) = 0$, a hybrid plant $\mathcal{H}_P$ for which there exists a continuously differentiable function $V : \mathbb{R}^{n_P} \rightarrow \mathbb{R}_{\geq 0}$ satisfying for some functions $\omega_c : \mathbb{R}^{m_{P,c}} \times \mathbb{R}^{n_P} \rightarrow \mathbb{R}$ and $\omega_d : \mathbb{R}^{m_{P,c}} \times \mathbb{R}^{n_P} \rightarrow \mathbb{R}$

$$\langle \nabla V(z), F_P(z, u_c) \rangle \leq \omega_c(u_c, z)$$
$$\forall (z, u_c) \in C \tag{5}$$
$$V(G_P(z, u_d)) - V(z) \leq \omega_d(u_d, z)$$
$$\forall (z, u_d) \in D \tag{6}$$

is said to be *passive with respect to a compact set* $\mathcal{A}$ if

$$(u_c, z) \mapsto \omega_c(u_c, z) = u_c^\top y_c \tag{7}$$
$$(u_d, z) \mapsto \omega_d(u_d, z) = u_d^\top y_d \tag{8}$$

The function V is the so-called *storage function*. If (5) holds with ω_c as in (7), and (6) holds with $\omega_d \equiv 0$, then the system is called *flow-passive*, i.e., the power inequality holds only during flows. If (5) holds with $\omega_c \equiv 0$, and (6) holds with ω_d as in (8), then the system is called *jump-passive*, i.e., the energy of the system decreases only during jumps.

Under additional detectability properties, these passivity notions can be used to design static output feedback controllers. The following result gives two design methods for hybrid plants.

Theorem 3 *Given a hybrid plant* $\mathcal{H}_P = (C_P, F_P, D_P, G_P, h_P)$ *satisfying*

(C1′) C_P *and* D_P *are closed sets;* F_P *and* G_P *are continuous; and* h_c *and* h_d *are continuous; and a compact set* $\mathcal{A}$, *we have:*

(1) If $\mathcal{H}_P$ *is flow-passive with respect to* $\mathcal{A}$ *with a storage function* V *that is positive definite with respect to* $\mathcal{A}$ *and has compact sublevel sets, and if there exists a continuous function* $\kappa_c : \mathbb{R}^{m_{P,c}} \to \mathbb{R}^{m_{P,c}}$, $y_c^\top \kappa_c(y_c) > 0$ *for all* $y_c \neq 0$, *such that the resulting closed-loop system with* $u_c = -\kappa_c(y_c)$ *and* $u_d \equiv 0$ *has the following properties:*

(1.1) The distance to $\mathcal{A}$ *is detectable relative to*

$$\{z \in \Pi(C_P) \cup \Pi(D_P) \cup G_P(D_P) :$$
$$h_c(z)^\top \kappa_c(h_c(z)) = 0, (z, -\kappa_c(h_c(z))) \in C_P\};$$

(1.2) Every complete solution ϕ *is such that, for some* $\delta > 0$ *and some* $J \in \mathbb{N}$, *we have* $t_{j+1} - t_j \geq \delta$ *for all* $j \geq J$;
then the control law $u_c = -\kappa_c(y_c)$, $u_d \equiv 0$ *renders* $\mathcal{A}$ *globally asymptotically stable.*

(2) If $\mathcal{H}_P$ *is jump-passive with respect to* $\mathcal{A}$ *with a storage function* V *that is positive definite with respect to* $\mathcal{A}$ *and has compact sublevel sets, and if there exists a continuous function* $\kappa_d : \mathbb{R}^{m_{P,d}} \to \mathbb{R}^{m_{P,d}}$, $y_d^\top \kappa_d(y_d) > 0$ *for all* $y_d \neq 0$, *such that the resulting closed-loop system with* $u_c \equiv 0$ *and* $u_d = -\kappa_d(y_d)$ *has the following properties:*

(2.1) The distance to $\mathcal{A}$ *is detectable relative to*

$$\{z \in \Pi(C_P) \cup \Pi(D_P) \cup G_P(D_P) :$$
$$h_d(z)^\top \kappa_d(h_d(z)) = 0, (z, -\kappa_d(h_d(z))) \in D_P\};$$

(2.2) Every complete solution ϕ *is Zeno;*
then the control law $u_d = -\kappa_d(y_d)$, $u_c \equiv 0$ *renders* $\mathcal{A}$ *globally asymptotically stable.*

Strict passivity notions can also be formulated for hybrid plants, including the special cases where the power inequalities hold only during flows or jumps. In particular, strict passivity and output strict passivity can be employed to assert asymptotic stability with zero inputs.

Tracking Control Design

While numerous control problems pertain to the stabilization of a set-point condition, at times, it is desired to stabilize the solutions to the plant to a time-upying trajectory. In this section, we consider the problem of designing a hybrid controller $\mathcal{H}_K$ for a hybrid plant $\mathcal{H}_P$ to *track* a given reference trajectory r (a hybrid arc). The notion of tracking is introduced below. We propose sufficient conditions that general hybrid plants and controllers should satisfy to solve such a problem. For simplicity, we consider tracking of state trajectories and that the hybrid controller can measure both the state of the plant z and the reference trajectory r; hence, $v = (z, r)$.

The particular approach used here consists of recasting the tracking control problem as a set stabilization problem for the closed-loop system $\mathcal{H}$. To do this, we embed the reference trajectory r into an augmented hybrid model for which it is possible to define a set capturing the condition that the plant tracks the given reference trajectory. This set is referred to as *the tracking set*. More precisely, given a reference $r : \operatorname{dom} r \to \mathbb{R}^{n_p}$, we define the set $\mathcal{T}_r$ collecting all of the points (t, j) in the domain of r at which r jumps, that is, every point $(t_j^r, j) \in \operatorname{dom} r$ such that $(t_j^r, j + 1) \in \operatorname{dom} r$. Then, the state of the closed loop $\mathcal{H}$ is augmented by the addition of states $\tau \in \mathbb{R}_{\geq 0}$ and $k \in \mathbb{N}$. The dynamics of the states τ and k are such that τ counts elapsed flow time, while k counts the number of jumps of $\mathcal{H}$; hence, during flows $\dot{\tau} = 1$ and $\dot{k} = 0$, while at jumps $\tau^+ = \tau$ and $k^+ = k + 1$. These new states are used to parameterize the given reference trajectory r, which is employed in the definition of the tracking set

$$\mathcal{A} = \{(z, \eta, \tau, k) \in \mathbb{R}^{n_P} \times \mathbb{R}^{n_K} \times \mathbb{R}_{\geq 0} \times \mathbb{N} :$$
$$z = r(\tau, k), \xi \in \Phi_K\} \tag{9}$$

This set is the target set to be stabilized for $\mathcal{H}$. The set $\Phi_K \subset \mathbb{R}^{n_K}$ in the definition of $\mathcal{A}$ is some closed set capturing the set of points asymptotically approached by the controller's state ξ.

The following result establishes a sufficient condition for stabilization of the tracking set

$\mathcal{A}$. For notational convenience, we define $x = (z, \xi, \tau, k)$,

$$C = \{x \,:\, (z, \kappa_c(\xi, z, r(\tau, k))) \in C_P,$$
$$\tau \in [t_k^r, t_{k+1}^r], (\xi, z, r(\tau, k)) \in C_K\}$$

$$F(z, \xi, \tau, k) = (F_P(z, \kappa_c(\xi, z, r(\tau, k))),$$
$$F_K(\xi, z, r(\tau, k)), 1, 0)$$

$$D = \{x \,:\, (z, \kappa_c(\xi, z, r(\tau, k))) \in D_P,$$
$$(\tau, k) \in \mathcal{T}_r\} \cup \{x \,:\, \tau \in$$
$$[t_k^r, t_{k+1}^r), (\xi, z, r(\tau, k)) \in D_K\}$$

$$G_1(z, \xi, \tau, k) = (G_P(z, \kappa_c(\xi, z, r(\tau, k))),$$
$$\xi, \tau, k + 1),$$

$$G_2(z, \xi, \tau, k) = (z, G_K(\xi, z, r(\tau, k)), \tau, k)$$

Theorem 4 *Given a complete reference trajectory $r : \operatorname{dom} r \to \mathbb{R}^{n_P}$ and associated tracking set $\mathcal{A}$ in (9), if there exists a hybrid controller $\mathcal{H}_K$ guaranteeing that*

(1) The jumps of r and $\mathcal{H}_P$ occur simultaneously;

(2) There exist a function $V : \mathbb{R}^{n_P} \times \mathbb{R}^{n_K} \times \mathbb{R}_{\geq 0} \times \mathbb{N} \to \mathbb{R}$ that is continuously differentiable; functions $\alpha_1, \alpha_2 \in \mathcal{K}_\infty$; and continuous, positive definite functions ρ_1, ρ_2, ρ_3 such that

(a) For all $(z, \xi, \tau, k) \in C \cup D \cup G_1(D) \cup G_2(D)$

$$\alpha_1(|(z, \xi, \tau, k)|_\mathcal{A}) \leq V(z, \xi, \tau, k)$$
$$\leq \alpha_2(|(z, \xi, \tau, k)|_\mathcal{A})$$

(b) For all $(z, \xi, \tau, k) \in C$ and all $\zeta \in F(z, \xi, \tau, k)$,

$$\langle \nabla V(z, \xi, \tau, k), \zeta \rangle \leq -\rho_1(|(z, \xi, \tau, k)|_\mathcal{A})$$

(c) For all $(z, \xi, \tau, k) \in D_1$ and all $\zeta \in G_1(z, \xi, \tau, k)$

$$V(\zeta) - V(z, \xi, \tau, k) \leq -\rho_2(|(z, \xi, \tau, k)|_\mathcal{A})$$

(d) For all $(z, \xi, \tau, k) \in D_2$ and all $\zeta \in G_2(z, \xi, \tau, k)$

$$V(\zeta) - V(z, \xi, \tau, k) \leq -\rho_3(|(z, \xi, \tau, k)|_\mathcal{A})$$

then $\mathcal{A}$ is globally asymptotically stable.

Theorem 4 imposes that the jumps of the plant and of the reference trajectory occur simultaneously. Though restrictive, at times, this property can be enforced by proper design of the controller.

Summary and Future Directions

Advances over the last decade on modeling and robust stability of hybrid dynamical systems (without control inputs) have paved the road for the development of systematic methods for the design of control algorithms for hybrid plants. The results selected for this short expository entry, along with recent efforts on multimode/logic-based control, event-based control, and backstepping, which were not covered here, contribute to that long-term goal. The future research direction includes the development of more powerful tracking control design methods, state observers, and optimal controllers for hybrid plants.
